THE AMERICAN EDITION

OF THE NEW

EDINBURGH ENCYCLOPÆDIA.

SCULPTURE.

The principle of imitation is founded deep in the nature of man—in nations—as in the individual early beginning to manifest a decided and happy influence. In the fine arts, this principle supplies at once the source of inspiration, and, to a certain extent, the standard of excellence. Viewed in their general tendency and design, poetry, painting, sculpture, architecture, and even music—all contemplate one end, namely, to awaken associated emotion; while each employs the same means of direct, or of less obvious imitation.

In none of the arts now mentioned, however, is imitation the final object or criterion of the exalted and most refined efforts of the artist. In all, imitation is merely the instrument of accomplishing high and peculiar effects; neither in the varied application of the common means does the individuality or essential character of each reside.

These positions conduct to important conclusions. It is not seldom assumed, that not only is imitation the origin of all art, but that the sole difference between its various branches lies in the manner of imitating. In short, that "painting is silent poetry—poetry, a speaking picture;" or, generally, that the abstract idea or image formed in the mind is identical in all, although particular arts may require diversified or even opposite modes of expression. This theory is partial and erroneous. In each of the arts, a distinction exists not in the manner alone, but still more essentially in the objects and extent of imitation; as also in the facility to be preserved of tracing the sensible architypes or primitive thoughts, on which the associated feeling is engrafted. The creations by which the poet rouses our sympathies, or sways our affections, often but faintly reflect living nature. Architecture, again, fills the mind with awe or delight, from recalling abstract and undefined perceptions of the majesty or grace of the material world. Musical imitation, though sweet and powerful in effect, is still more vague in principle, and more mysteriously associates the corporeal with the intellectual universe. These arts are thus placed widely remote from the direct imitations and definite aims of painting and of sculpture.

A twofold division of the arts of imitation is thus discovered arising from a constitutional distinction in their common and animating principle. To those of one class, embracing poetry, music, and architecture, may be appropriated the name "imitative arts:" while painting and sculpture may not improperly be distinguished as "the arts of design." These terms appear sufficiently expressive of the essential difference between the two divisions—the associated impression in the former depending upon general imitation only, while the latter requires a faithful delineation of perfect, doubtless, yet of living nature. In the following pages, the appellation of "fine arts" is exclusively applied to those of the second class.

Painting and Sculpture, although thus assimilated as constituting one of the grand divisions of art, and consequently exhibiting a certain resemblance in their leading principles, are yet discriminated by marked and peculiar characters. In the latter, form and expression constitute the only legitimate objects of imitation; in the former, the representation includes every attribute of external nature. Extent, in the first, always in one, frequently in every direction, is produced by rules of art, abstractly unreal, though true in effect; in the second, dimension and irregularity of superficies are actually exhibited in absolute or proportional magnitude. Sculpture is more severe, simple, and veracious; Painting more animated and varied, though illusory and conventional in its modes. This imitates, that represents. Though from the addition of colour, as a third element of design, the imitation be more lively, and generally more pleasing than the representation; yet, in respect to intellectual gratification, it may be justly questioned whether the inventions of sculpture do not afford the nobler and more refined enjoyment.

These arts have likewise their points of union as well as of contrast. They happily illustrate the observation of Cicero regarding the mutual blending of the different provinces of human pursuit. In the chart which exhibits the empire of genius, the central portion of each division is strongly marked, but the distant confines melt into each other, nor is it easy to ascertain with precision the exact boundary. Thus in sculpture, relievo approaches the varied composition and illusive effects of painting and perspective, while in simple chiar'oscuro, painting adds nothing, save fiction, to the elements of the sister art. But an important distinction is here to be remarked. While the painter derives power from borrowing the simplicity and learned outline of sculpture, even should his works, like those of the Roman masters and fathers of the art, thus acquire a degree of harshness; yet the sculptor cannot transplant one charm peculiar to painting which does not become a meretricious ornament, detracting equally from the unity and dignity of his composition.

Sculpture, or the actual representation of form by its tangible properties, being the more obvious in application, and the easier in execution, was most probably the earlier cultivated of the arts of design.

Respecting its origin, much has been written, great ingenuity displayed, and authors have claimed for various favourite nations the praise of invention. The same remark applies equally to all the arts. But here theory appears to be not more judiciously applied, than would be speculations on the priority of inventing sight or hearing. Poetry and music—sculpture and painting, each has its spring in a law of human nature, whose necessary operation is to create desires which point to the respective objects of these arts. The imagination only requires to be stimulated by desire, whether natural or artificial, quickly to discover the means of gratification. Accordingly, we shall find it more agreeable to fact, as it certainly is the simpler and more philosophical view, to regard every art as arising insensibly among different nations, and as cultivated independently, though with unequal success, from the earliest period. Nor is similarity of style evidence of continuous imitation. In the infancy of society, men in all countries resemble each other very closely; their wants are the same, their means of supplying these at first but little varied, and the progress from the naked and uninformed savage, to the possessor of some degree of knowledge and of social comfort, is marked by nearly similar gradations. The primitive efforts of invention among every people, as compared with those of other and distant nations, will consequently present little of diversified or peculiar character. The first statues of Egypt and of Greece exhibit almost identical lineaments, and even corresponding attitude,—simply because each had to contend against the same difficulties, with nearly equal facilities of surmounting them. If imperfect instruments, unyielding materials, and inexperience of hand, obliged the Egyptian artist to represent his figures in a constrained posture, with the knees pressed together, arms hanging down and close to the sides, and this not even in the earliest state of the art; the same restraints imposed a similar mode of representation on the Grecian, although from the operation of external causes the advance of genius was very unequal in the two countries. Surely then it is little less unphilosophical to maintain, that the latter must have been a copyist of the former, than it would be to assert that the wigwam, on the shores of the Maragnon or the Illinois, must have been borrowed from the same plan as the aboriginal hut which subsequently rose into the temple and the portico on the banks of the Eurotas or Cephisus. The hut and the wigwam are antitypes of each other, because both are the same primordial rudiment of an art having its scanty origin in necessity, before exalted by taste into a source of beauty and of grandeur. The idols of the Hindoos, the carvings of the South Sea islanders, are not unlike to descriptions of the early images of Greece, sculptured by the predecessors of Phidias and of Praxiteles. Does this resemblance arise from reciprocal imitation, from a common instructor? Consistency would require an affirmative reply. But with equal probability might it be assumed, that the harmonious language and no mean strains of the Malay bard, are derived from Ionia and from Homer.*

All these kindred arts owe their birth to the same law of necessity—necessity of ministering—not to the wants of the body, but to the more ardent aspirations of the heart and of the affections—to piety, to patriotism, to friendship. In this view, though with excusable vanity they assigned to their own country the earliest knowledge of those delightful pursuits, the Greeks evinced a true feeling of their native original, by veiling these claims in beautiful allegory. To love, under which name every noble emotion was included, the ancient poets attributed the gift of the arts.

The historian of Sculpture, therefore, who desires to render his labours useful, will, with judicious humility, limit inquiry to a simple endeavour to trace the progress and improvement of the art among the different nations of antiquity. To amuse with theories of its origin, however ingenious or profound these may appear, is in reality to stop short with a partial view of facts, when a general law is within reach. But in one respect is observed a very marked distinction in the claims of separate states. In the relative degrees of excellence attained there is found a striking diversity; as also in the length of time passed in realizing the same advances. This inequality it will be especially requisite to notice, while an attempt to explain the cause may lead to results of utility in the philosophy of art, exhibiting the union which exists between moral improvement and the lofty exercises of genius, as depending on the political happiness and condition of man.

In arranging the historical details of any art also, or of any intellectual pursuit, the simple order of time will generally be found most congenial with the connection of events, and the most instructive to the

* The Malayese, instead of being the most cruel of cannibals, as long represented, are now known, when treated as human beings, to be exceedingly docile and affectionate in disposition. They delight in the exercises of music and poetry, and speak a language which, from its elegance and harmony, has been styled "the Italian of the East."

The early and lamented death of the late William Jack, Esq. H. E. C. S. the chosen friend and companion of the enlightened and patriotic Sir J. Stamford Raffles, with the subsequent loss of his numerous manuscripts on board the *Fame*, has deprived Europe of rare and valuable information on the inhabitants, productions, and literature of the Eastern Archipelago. To the causes of public and private regret for genius and worth removed in the prime of manhood, this is no small addition; for to this most interesting and novel subject, with many advantages, Mr. Jack is known to have applied, with wonted ardour, the brilliant and varied powers of his accomplished mind. The press, both of Europe and of Asia, has, on this mournful subject, already expressed a sympathising homage; yet it is to be hoped that some memorial more generally accessible may appear—not for the sake of the departed, whose virtues and talents are recorded in the congenial bosoms he most loved, but to be an example and encouragement to the living.

reader. The epochs and eras of art, according to which writers have too frequently divided, rather than classed their materials, where discernible at all, may more commodiously be resolved into gradual changes, while not unfrequently they seem altogether imaginary. The influence of some strong and determining impulse, operating a sudden effect on the style and character of invention or improvement, is to be found occasionally in the progress of individual eminence: but the advance or decline of general acquirement is on the whole equable and consecutive—less dependent on particular occurrences, whether felicitous or adverse, than on the richness or poverty of successive discovery.

In the spirit of these observations, it shall be our object in the following pages to trace the history of Sculpture through the divisions of ancient and modern art. The first part will be occupied with the narrative of its neglect or encouragement, of excellence and decay, in Egypt and the East, among the Greeks, in Etruria, under the Cæsars, till the extinction of letters and refinement in Europe. With the rise of the Italian republics we hail the reappearance of Sculpture, and from the 10th to the 19th century, a series of interesting, but often melancholy events, will form the subject of the second part, and close the history with the labours of contemporaries. Our limits necessarily impose brevity in all instances. In many we shall merely touch upon the leading facts; and in that particular section the state of the art in Greece will include every thing valuable in the ages of antiquity. In part second, the 15th and 16th century, and our own times, adorned by the names of Canova, Flaxman, Thorwaldson, will demand pre-eminent regard.

PART I.

ANCIENT SCULPTURE.

SECTION I.—*Egyptian Sculpture.*

Although the sacred Scriptures, in all cases the earliest and purest fountain of truth, contain the first authentic memorials of Sculpture, we prefer commencing with some account of Egyptian art. In drawing conclusions from monuments actually in existence, many of which we have seen and examined, while no Jewish remain is now to be discovered, regularity will thus better be preserved. An examination also of the style and character observable in the sculptures of Egypt, appears to offer some assistance in collecting the scattered lights which the uncertain touch of scanty or dubious history flings over the mysterious ruins amid which the arts of Babylon and of Persia have been seated.

Egypt, in art, in science, in government, stands alone among the nations of the ancient world. The distinction is, however, a melancholy one, pointing to early promise unproductive of final eminence, and ending in disappointment. In almost evèry mode of intellectual exercise, as in every species of knowledge, she had made the first advances long before those states destined to outstrip her had started in the career. But in all these respects, and especially as regards the progress of art, the singularity of her fate is remarkable in this, that the genius which had received or discovered the first principles, continued in activity and in constant employment on undertakings of magnificence, without progressing—without partaking in the general enlightment derived in many instances from the example of its own success. Egypt, perhaps with justice, has been called the cradle of the arts, understanding by that expression simply priority of cultivation; yet in this their aboriginal seat, during a period of eighteen centuries, from Menes to Alexander, they hardly attained a maturity beyond mere infancy, as regards the higher capabilities of invention. During a far shorter interval in other climes, sculpture in particular had reached the perfection of ideal beauty. While the utmost skill of the Greek artist was rudely capable of fashioning into a square pillar the representations of his country's divinities, the objects of the Egyptian's veneration had assumed no mean resemblance of the human or conventional form. On the other hand, when the sublime works of a refined age had in Greece almost exalted superstition into sentiment, the worshipper in the temples of Memphis and of Thebes still bowed before the hideous deities of his ancestors. "For seven thousand years," says Pausanias, "Egyptian sculpture remained unchanged." The exaggeration proves the truth of the preceding observations, and shows that the absence of improvement had not escaped the notice of those who were more nearly contemporaries, and had examined in their almost perfect state the works from which they deduced the conclusion.

Whence then originated this hostile and chilling influence which arrested knowledge in mid-progress, which blasted refinement in the very bud? The answer to this question involves the fate, and will best explain the history of Egyptian sculpture.

The causes of improvement or of decline in the arts have too seldom been sought where only they are to be found—in the objects and character of national polity. To ascribe their cultivation to climate—to disposition, to opportunity of studying beautiful nature—to patronage—to commerce, is to carry inquiry no further than secondary, and at best but favourable influences; to elevate into causes, effects which regularly proceed from the paramount operation of legislative institutions. Some observations on this subject are the more necessary, that the imperfection of sculpture in the East, and in Egypt especially, has been attributed to deficiency in those minor and less influential considerations, which may become accessory, never preliminary means of success, or sources of invention.

The government of ancient Egypt, though styled, and perhaps esteemed monarchical, was in reality a theocracy—and in its most rigid, most paralysing form. All knowledge, and consequently all substantial power, rested in the hands of the priests, who constituted a separate order, regulated by distinct laws, and holding communication, and preserving intelligence by means unknown to the people, or even to the sovereign. The members of the hierarchy thus became not only the first legislators, but the precepts being written in a sacred and symbolical language, intelligible only to themselves, they of necessity remained possessors of the exposition, true or false, real or occasional of the primitive laws. In such a state of things the whole nation were the subjects, and kings merely instruments under the control of those who were at once the sole depositaries of human authority as also interpreters of the will of heaven. To be perfect, such a system wanted only permanency, and this requisite, except against foreign conquest, was effectually secured. The laws immutable and inexorable, of which the priesthood were the guardians, chained down every form, institution, or practice, once established; determining for ever the condition, and even profession of each family, and of every individual. Religion, business, pleasure, had each allotted hours and prescribed regulations. Free and voluntary action was unknown; legal inquisition penetrated even that sacred circle, and regulated the duties of domestic privacy. National polity to the minutest details was to be unchanged and unchangeable; like the celestial bodies, whose motions formed the grand object of national science, it was to revolve eternally in the same circle. Nothing once connected with the system was to suffer decay, and as has been well observed, the very bodies of the dead were to be rendered imperishable.

In contemplating such a system, although we acknowledge the influence of an awful and stern sublimity, yet the feeling is not of that elevating description which grandeur, whether moral or physical, generally inspires. The mind, on the contrary, experiences a depressing, an overwhelming sense of individual helplessness; while, on its immediate subjects, the operation of such a government must inevitably have been, to produce a gloomy sameness of character, and the most heartless mediocrity of intellect. To improvement of a certain extent in the severer sciences, and in accordance with received opinions, it was not unfriendly; for success in abstract speculation depends not on enthusiasm which is kindled by external appliances, nor on the tenderer inspirations of sensibility. But to those elegant arts which derive their existence and perfection from the susceptibilities of imagination, from the free breathings of genius —the system was death.

Accordingly, in whatever refines, elevates, or soothes the heart, Egyptian art, as appears from the Greek historians, was extremely deficient. In their music and poetry, as in their painting and sculpture, human affections had no place; the modes were severe, unalterable, and consecrated solely to a gloomy and unideal religion. Hence the "bitter Egypt" of the Greeks, not as some explain, indicating the natural saltness of the soil, but because those arts, so cherished them, which are at once the creation and the solace of sensibility in ardent and exalted minds, there languished and were repressed.

To the progress of architecture, indeed, in some essential respects, this stern polity was not unfriendly. In this art, the principles though few, give rise in their varied combination to more than one source of intellectual pleasure. In the Grecian temple are found beauty, grace, proportion, simplicity, harmony, extent. In the mysterious structures of Egypt vastness and simplicity are the only elements discernible of the grand. From these, however, the most powerful, if not the most refined and agreeable emotions are experienced; long withdrawing lines, unbroken surfaces, large masses, simple contours, even should the individual forms be destitute of proportion and grace, will always produce grand and solemn effects, capable of being carried to the majestic and sublime. Thus in viewing the temples scattered over the Thebaid, those very edifices characterised by Strabo as "barbarous monuments of painful labour;"—in contemplating the pyramids whose outline is without variety or contrast, the imagination is exalted to a high pitch of awe and astonishment. But these lofty effects arise from a principle merely accidental, they are not the fruits of intrinsic science or of refined art; they are the inevitable, not the meditated consequents of the system we have described. The eternal durability, to which in all their designs and institutions the hierarchy aspired, necessarily pointed out the selection of a style of architecture, retaining, as the most substantial, only the simplest forms and the largest masses.

These remarks, and our observations generally on the tendency and spirit of Egyptian government as regards the arts, are farther corroborated by the fact, that even to their very measurements, all the sacred edifices of ancient Egypt appear to have been constructed on one and the same unvarying model; without accommodation whatsoever to situation or circumstances.

A system, whose influence thus produced a species of sublimity in architecture, would operate fatally upon sculpture. Attention to durability, regardless of elegance as a primary object, enormous masses and extended lines, so imposing in the former, would, in the latter, produce rigid and motionless figures, devoid of sentiment as without beauty. Such, accordingly, is the character of the genuine monuments of Egyptian statuary. The essential elements of the beautiful are present—simplicity and breadth; but beauty is not elicited; it is the simple uninspired by any feeling of the true, the natural or the graceful; breadth without harmony or proportion of parts, exhibiting lifeless and inert magnitude. A remark bearing on their arts generally may, with peculiar propriety, be applied to the sculptures of the Egyptians, that in these we see only the records of power, of patience, and of labour, not the creations of mind, of taste, or of genius. But sculpture among this people laboured under particular disadvantages. It was considered as exclusively attached to religion, and employed in representations of divinities, priests, and kings—personages to whom only statues were allowed to be erected, for the figures to be found in tombs appear to have been merely symbolical decorations. Now in all these, even in the last, the forms, modes, and expressions were unalterably fixed—and fixed too from types frequently of the most hideous description, at best ill imagined and little adapted to the objects and spirit of the art. This religion also, to the consecration of whose absurdities the noblest of the arts was thus enslaved, was wholly metaphysical and allegorical, not admitting hero-worship, which, by mingling images of human sympathy and virtue, with abstract and exalted conceptions, tended so materially to elevate the style of composition among the Greeks. The Egyptian artist, therefore, even had he been permitted to deviate from his model, had no inducement, and no ennobling source whence to derive beauty. Imagination wanted materials, which neither the subject nor living nature, as he saw it, could supply. Again, sculpture not only suffered from the general disadvantage of hereditary and unchanging professions, a regulation which repressed every thing like the successful predilections of genius; but as a farther security against the possibility of innovation, slaves educated under the eye of the priests were entrusted with the execution of the most sacred, and, consequently, most splendid and important monuments. The art was thus degraded into a servile occupation, and the last hopes of eminence, honour and independent reward, extinguished.

These general remarks will, in some measure, supply an explanation of many leading facts, on which much misconception has prevailed, as regards both the perfection and the epochs of sculpture among the Egyptians. Opportunities will occur hereafter of marking the due application of the lights thus obtained. In the meantime it may be observed, that the fact so often quoted to prove the excellence of art amongst this people, and of their posessing unerring canons of proportion, namely, that statues composed of different pieces, worked by distant artists, were yet so accurately wrought as to fit exactly when united,—if it establish any thing, it is the truth of the preceding observations, and the existence of that o'ermastering despotism we have noticed. For granting the fact, of the truth of which many doubts might be suggested, on any theory of natural imitation, it is impossible; such mechanical correctness could be attained only where the simplest and most rigid attitudes were fixed by unchanging prescription.

As respects the eras of Egyptian art, accurate discrimination has rarely been attempted. From the earliest times, down to the reign of the Cæsars, all statues imitating that peculiar manner, have by some been classed as works by Egyptian sculptors, or at least have been adduced as examples of their style; while by others, minute and often imaginary differences have been erected into permanent distinctions; and epochs and revolutions of taste and execution assumed, which cannot be substantiated from the scanty remains of this interesting but mysterious antiquity.

Two sources evidently remain to us of judging, with sufficient accuracy, the labours of the sculptors of Thebes and of Memphis,—in the ruins scattered throughout upper Egypt—and in the numerous specimens preserved in the galleries of Europe. This latter source derives new importance from the recent additions to the British museum; these not only enable us to contemplate some of the most perfect monuments of Egyptian art, but likewise afford standards for appreciating and classing the specimens of other collections.

The vestiges of the greatness and refinement of ancient Egypt are dispersed over a narrow district, extending on both banks of the Nile from the twenty-third to the thirty-first degree of southern latitude. The island of Phylee, near the cataracts and the ruins of Sais, in the western Delta, may be considered as the boundaries on the south and north of this mysterious vale;—where, amid the wreck of cities, temples, pyramids, and tombs, monuments of forgotten wisdom and departed power, sleep the early generations of the humane race,—where Moses, and Plato, and Euclid studied.

The progress of colonization or of conquest has followed the course of the Nile northwards: the purest, therefore, because the oldest examples of native taste and skill in the arts are to be looked for in the works of the upper Thebaid, in the temples of Phylee, the sculptured excavations of Elephantis, the tombs of the kings, and in the stupendous edifices of Carnac and Luxor. In this view the pyramids, as they adorn the neighbourhood of Memphis, the second seat of empire, situate much farther north, and built long after the splendour of Thebes, the first capital, had passed away, must be regarded as belonging to a more recent age. Into this question, however, it is not our province to enter; nor particularly to describe these remains which, scattered over a length of more than five hundred miles, still strike with wonder and with awe. But among the people of whom we now speak, sculpture appears to have been inseparably associated with architecture; a mode of determining the relative antiquity of works in the former is thus ascertained.

The eras of sculpture in Egypt, as already observed, have been very differently stated. The division of Winklemann is the most simple and perspicuous, and on the whole possesses the greatest share of historical correctness. Still the method is not free from the common objection, that it pays not due regard to the revolutions of native art as distinguished from that excellence subsequently introduced and engrafted upon the national style. This system, therefore, as well as every other, we are forced to abandon for the same reason, and to adopt the following, which, with some degree of novelty, will, it is hoped, be recommended by the more useful advantages of truth and simplicity, and by at once presenting an argument resting upon, while it discriminates intrinsic distinctions.

I. Era of original or native Sculpture.
II. Era of mixed or Greco-Egyptian Sculpture.
III. Era of imitative Sculpture, improperly denominated Egyptian.

I. From the above division of the subject it will appear that we admit only one age of art purely Egyptian; that is, during which sculpture can be considered truly indigenous, without any foreign admixture. The two remaining epochas are added, in order to embrace the consideration of those details which have been hitherto regarded as forming constituent parts of the Egyptian school, though in fact but partially connected therewith, and not unfrequently pertaining to works which, except in rude materials, had never been out of Italy, and never handled, except by Greek or Roman artists. The first or true epoch of sculpture in Egypt ascends from the conquest of Cambyses, till all records are lost in the remoteness of antiquity. During this period only were original institutions in full vigour, and public works conducted by national energy, and stamped with national taste.

In illustration of these views, it first becomes necessary to examine whether the resources of the state and the ingenuity of the people, were adequate to the production of the numerous and stupendous works, which must thus be ascribed to the first age. Not only is the answer to this inquiry in the affirmative, but with no degree probability can any other date of erection be assigned. We learn from Homer, that in the time of the Trojan war, twelve centuries anterior to our era, Thebes was one of the most magnificent cities then in the world; indeed the terms of the description would induce the belief of its paramount grandeur. Again, from himself we know that Herodotus admired these very monuments, the ruins of which excite the wonder of present times. This father of history visited Egypt not quite a century after the reduction of that country by Cambyses. Even then the origin of these structures was lost in the obscurity of distant time; consequently they could not be the erections of an age later than this monarch, who in fact laboured to destroy them. They were on the contrary universally attributed to the reigns of the early native princes; of whom Herodotus attempts a long though imperfect enumeration, prior even to Sesostris. Carrying these pretensions to antiquity no higher than Homer's description, which corresponds with the era of Sesostris, we thus gain two fixed points, which supply an interval of seven hundred years from the war of Troy to the invasion of Cambyses, that is from 1200 to 526, B. C. During the lapse of so many ages, the whole power and riches of Egypt were placed at the disposal of a society of men whose wisdom and learning were proverbial, and whose intelligent and active ambition these very monuments testify. Anciently Egypt was likewise remarkably populous, so as to occasion a saying, "that instead of beauty nature had conferred upon its women the more honourable gift of fertility." Enjoying for a long period the entire commerce of the ancient world, the wealth of this country must always have been great. Even when reduced into a Roman province, and despoiled of much of its original importance, the amount of public revenue under the Antonines was 12500 talents, or two millions and a half sterling—equivalent to a much larger sum. Of the capabilities, both physical and intellectual, of the ancient inhabitants of Egypt to produce the works in question, there can thus exist no reasonable doubts; while by the testimony of history, their erection is restricted to a period not later than now assigned; but if necessary, we might ascend much higher.

We have thus ascertained the limits within which the primitive school of sculpture in Egypt must have flourished; for in most instances its labours are attached to, and consequently have been completed at the same time with the architectural remains, of which they have once constituted the profuse and even lavish ornaments. We are thus enabled to proceed, with no small degree of certainty, to the examination of the genius, character, and principles of this aboriginal style. Here the examples may be classed under three divisions; first, colossal statues; secondly, single figures or groups, about the natural size; and, thirdly, hieroglyphical and historical relievos. In each of these, however, is to be discerned a similar character of invention and finishing, varied only in the degree of excellence or nature of the work. Minuteness of individual description is therefore less necessary.

The works of the first class, many of which still remain both entire and in ruins, from their magnitude fix our earliest attention. Indeed, than a statue of granite sixty feet high, there hardly exists an undertaking more laborious or difficult, or an instance more striking of disregard of time and patience of toil. Of these enormous sculptures, some have been rocks hewn into shape alone, and left adhering by their base to the living bed. Of this class the celebrated sphynx ninety-five feet long and thirty-eight high, is an example. Others, as the figures in the Memnonium among the ruins of Thebes, have been built of square blocks, first built and afterwards carved into form. The greater number have been sculptured from an entire block finished in the quarries of Upper Egypt, and transported to their site by the waters of the Nile. Most of the smaller works of this age are in sandstone and other softer materials, such as the situation naturally afforded; the great statues are universally of granite, seeming to indicate that in their construction time was disregarded that eternity might be secured.

Of these colossal sculptures, the most remarkable, or at least the best known to general readers, are the two statues still remaining in the Memnonium. Exclusive of the lower plinth of the rude throne on which it is seated, the altitude of each is fifty feet high; but between the two, and scattered around to some distance, lie the ruins of a still more gigantic figure of red granite. These, by Denon and others, are conjectured to be the remains of the celebrated sounding statue of Memnon, a supposition which is opposed by the inscriptions on one of the others, but is corroborated by the head now in the British museum—the most splendid specimen of this primitive style in Europe. In both figures the position is exactly the same and may be described as common to all works of this class; the head looking straight forward, arms pressed close to the sides, and hand expanded resting upon either knee, lower limbs perpendicular and apart. This attitude, as will at once be perceived, is little calculated to convey any sentiment of ease or of grace; the whole effect, indeed, is stiffness and constraint. Yet, in these vast though uninformed labours, united as they are with dim and distant recollection, there is something mysteriously grand and solemn. Nor is this produced by association alone. For while it is to be remarked of colossal statues generally, that they exhibit the greatest comparative perfection to which Egyptian sculpture has attained; in them we likewise discover visible approaches to truth and nature, with occasionally, as in the sphynx and the head of Memnon, considerable feeling of the sweet, the tranquil, and the flowing, expression, and contour.

In the second class appear to be comprehended both the earliest and the latest of Egyptian statues. The infant efforts of the art seem to have been exercises on pieces hewn from the living rock, in the process of enlarging or of forming those natural caverns or artificial excavations which were the original scenes of all solemn assemblies and religious festivals, prior to the erection of temples; and during every age, the adorned repositories of the dead. Afterwards statues, thus formed, were loosened from their bed to be transported to distant situations, or were sculptured, in what finally became the general mode, from detached blocks. It is not here intended to imply that these two manners are decidedly to be separated, or that the former, being discontinued, was superseded by the latter, but simply to express the fact of priority, sufficiently obvious from the habits and history of the people. Hence, perhaps, a circumstance may be explained, intimately connected with the subject, and which has given rise to much discussion. In all Egyptian statues of every proportion, and in every attitude, a pilaster is found at the bank as if supporting the figure. Now in all works belonging to the first manner, the ground is never entirely removed, the posterior portion always remaining undetached; while if the statue has been formed by cutting round it to a recess behind, a pilaster is carried upwards to the ceiling, evidently with the original view of increasing strength.

Subsequenly, from that hostility to innovation characterising the system, partly to avoid difficulties of execution, and to obtain a plane surface for the inscription of hieroglyphics, the aboriginal pillar was retained. Of these two manners in figures composing the second class, numerous specimens remain, especially of the first, as in the excavations of Philee, Elephantis, Silsilis, and in the tombs of the kings. These also are not only the most ancient but likewise the most authentic; and there can be no question, that of the second kind, many in the different cabinets of Europe are spurious imitations of Egyptian art. In the genuine statues of both kinds still existing on their native site much diversity of style and character prevails. The varieties, however, cannot be reduced to any determinate epochas, or regular gradations, as has sometimes been attempted. From the contradictions in time and vicinity of situation in the good and the bad, the disparity in point of merit can properly be ascribed only to individual excellence or mediocrity in the artists employed—to the purposes contemplated—to the opulence or taste of the projectors.

The profusion with which Relievos were employed merely as decorative parts, without regard to intrinsic beauty, as also the nature of hieroglyphical representation, where only a general resemblance of outline was studied to the neglect of expression, and the more delicate varieties of form,—necessarily exerted a prejudicial influence not only in this department, but generally on the progress of Egyptian sculpture. In this branch of the art, likewise, as might be expected, where, from the introduction of a number of figures, other principles of design, besides a mere knowledge of form become necessary, the deficiencies of the artist are betrayed more conspicuously. This, however, must be understood with due limitation. In such relievos, sepulchral ones for instance, as contain few figures, seldom more than three, and in which the attitude is simple, without violent or complicated action, are frequently displayed no mean beauties of execution and of outline. But on the contrary, in historical relievos, which frequently cover entire walls of immense edifices, representing processions, battles, sieges, all is confusion, feebleness, and puerility. In the drawing and anatomy the utmost ignorance is manifested; the figures are without joint, and exhibit not the slightest knowledge of balance or spring in motion. Even proportion and magnitude, not to mention perspective, seem to have been utterly disregarded or unknown. The military engines, buildings, soldiers, all appear of the same size, and all equally near the eye. The hero is certainly distinguished from the rest, but in a way which marks the absence of all science, and indeed could be conceived or tolerated only among a people whose taste was in the highest degree barbarous. This personage, who is generally in the bloom of youth, that he may stand forth from the vulgar, is always represented at least double the stature of his followers. The circumstance of confounding moral with physical greatness is alone sufficient evidence of the infancy of invention, and proves the Egyptians never to have passed that limit where, by a slight refinement of imitative tact, if the expression may be permitted, a tolerable resemblance of individual form is accomplished, but where any sustained efforts of abstract imitation is impossible. The hieroglyphics, which form so large a portion of the Egyptian relievos, we have already noticed as destitute of accurate discrimination of form, considered as works of art; but to this latter rank they ought hardly to be elevated; they are more properly to be regarded as conventional representations, dependent on modes and principles equally arbitrary. The praises bestowed on works of this class by Winkleman and others, are to be restricted to the mere excellencies of labour and workmanship. Even in these respects the commendation is often exaggerated, not unfrequently misplaced. The genuine relievos of the primitive age are, without exception, anaglyphics, that is, raised on themselves, but depressed beneath the general surface on which they are engraven. Now we cannot admit the refinement so generally presumed in this fact, which is considered as evidence of elegant invention, both to deepen the effect to a spectator at a distance, and to guard the work against the injuries of time. The latter of these reasons may be true, certainly, not the former; for if the shadow be thus stronger, it obscures in an equal degree the contours of the niched figure; also the practice is universal, as well in works which are to be viewed near, as in those placed remote from the eye. This manner, therefore, is to be regarded as originating in the limited resources of an imperfect art. It is in truth but the first step in improving in the earliest and rudest of all sculpture, often to be met with in the oldest monuments of this very people, namely, a simple outline of the object very deeply cut on a plane surface. An obvious advance was to round the included figure, marking the salient parts, and depressing the hollows. The next step, but more laborious and difficult, especially in hard materials, was to remove the ground, leaving the figures in full and bold relief. This view is so strongly corroborated by the history of the art in Egypt, that any work in relief of the description, properly so called, must be assigned to a later era. From not attending to these circumstances, writers have built very erroneous theories on some specimens of bas relief of the usual kind found in the pyramids. These were internal decorations merely, and show that the interior of these structures had in some instances been adorned long after their erection.

Our observations have hitherto been confined to the primitive ages, and we have dwelt longer on this period for two reasons. This being the true era of Egyptian sculpture, properly so styled, the preceding remarks have nearly exhausted whatever of interest strictly belongs to the subject; again, few important and authentic monuments of any later date now remain. The second epoch will therefore not long detain attention. The expression mixed art, which has been selected to distinguish this epoch, appears sufficiently discriminative, and marks the engrafting of different tastes and styles upon the ancient modes that took place on the conquest of Cambyses, and subsequently under Alexander and his successors. In both cases a change was certainly experienced, still the ancient character predominated: indeed the grounds, already explained, on which it was founded were too deeply laid, easily to be shaken. To have introduced any radical innovation, not only the frame of society must have been dissolved, but the very existence of the nation must have ceased. Under the Persians, as regards sculpture, we conceive, contrary to so many opinions hazarded in opposition, that no actual additions were made. The influence exerted by their dominion on the art, amounted merely to a negative, to the prohibition of its exercise, the destruction of its early and best monuments, and a consequent deterioration in the few and feeble attempts by artists during the latter years of that dynasty. Mythraism, the prevailing religion of the conquerors, prescribed the use of statues, where only they had been previously allowed. Architecture was the only art extensively practised. But the Persian erections were modifications of materials torn from the mighty structures of former ages, not original efforts. Here the impress of the ancient style could not be effaced; while the sculptural embellishments permitted relievos exactly of that description in which the Egyptian artists were the least skilled, and also which was calculated to deteriorate, not to improve.

In little more than a century and a half the empire of the Persians was subverted by the Greeks. But in Alexander the ancient arts of Egypt found not a patron. The majestic range of cities, temples, and palaces, which bordered the sacred stream of the Nile, became so many quarries of tempting access, whence Alexandria was reared; and the mightiest as well as most rational trophy of Grecian superiority borrowed its grandest and most enduring monuments from the stupendous labours of the first age. The successors of the Macedonian prince pursued the same system; and though in seclusion the Ptolemys might have enjoyed the polished representations of her arts, and cultivated the learning of Greece, we do not find that beyond the precincts of the palace any remarkable effects of their refinement are visible, at least in the statuary of this period. The character in all essential respects remained Egpytian. Nor if considered, as the arts always ought to be, in relation to the political system, could this fate be otherwise. The objects, purposes, and forms of Egyptian sculpture had long been fixed, and by that very polity and religion now again partially re-established, in as far as respected the subject under review. We would ascribe then the amelioration of taste and practice, which certainly is to be observed under the Grecian princes, principally to the removal of the restrictions introduced during the Persian conquest, and the renewed splendour of the ancient worship; for as already shown, to sacred purposes only were the magnificent displays of the art devoted. It is not, however, to be denied, that amid the strongly marked features of indigenous character are to be perceived in the sculpture of this era, approaches to a firmer, more natural and bolder style of design, which can be attributed only to an intercourse with Greece. This improvement is most conspicuous in the clothing and action of figures. The drapery, instead of being glued as it were to the body, and in the female deities barely distinguishable, by a few small and rigid plaits, now becomes more full and flowing, with some faint indication of selected arrangement. The attitudes exhibit more of mobility, the arms are farther separated from the sides, and the whole design more easy, vigorous, and decided. The chiseling also displays more of energy, but the forms are still destitute of style in composition, and discover not the slightest traces of any abstract principle of beauty, either natural or ideal.

These brief notices have conducted us rapidly over a course of many centuries, to the third and last era, that of imitative art, under the dominion of the Romans. This epoch may be considered as commencing with the introduction of Isiac mysteries at Rome; but as marking a distinct character in the history of art, the principal works by which it was distinguished are to be referred chiefly to the reign of Hadrian. These works, in strict propriety, have no real connection with Egyptian sculpture. During his abode of two years in that province, and especially by the deification there of his favourite Antinous, this emperor appears to have imbibed a fondness for the arts of Egypt. He accordingly caused imitations of the sacred statuary of the East to be executed; and formed in the Canopus, or Egyptian Gallery of his villa, a very complete and numerous collection. The taste was followed, as might naturally be expected, by the wealthy of his subjects, and imitations were multiplied over the empire. But although these sculptures were modelled after the most ancient of the Egyptian forms, the attributes carefully preserved, and even the material, such as basalt, porphyry, granite, brought from natural quarries, yet the artists were Greeks or Italians, and the Grecian character of design is visible in every remaining specimen whose merits entitle it to criticism. Nothing therefore can be more futile than from these works to deduce conclusions regarding the merits or principles of the art as practised by natives, and in the early ages. It is only in compliance with classing certain details, and from a desire to include under one head whatever has been connected with this particular part of our subject, that this era has not consequently been introduced among the corruptions of Greek art. So far indeed does our scepticism here extend, that we doubt whether a single statue near the natural size of genuine Egyptian workmanship has ever been disinterred in Italy or in Europe. Certainly, we are induced from inspection to pronounce the smaller figures in the different Italian collections as belonging to this last period, while the others, however celebrated, such as the Isis of the capitol, are of such a style, or rather so destitute of all style, that they may belong to any or to no era. A distinction indeed has been attempted to be established, from the circumstance, that these latter compositions are unadorned by hieroglyphics, and have no pilaster behind. But it will surely be admitted that these accessories would not be more difficult to add, than to imitate the whole form and attitude, and that wherever complete imitation was requisite, these attributes likewise would be affixed.

From the preceding account it will appear, that of the various eras under which the history of Egyptian art has been reduced, one only, extending from the earliest records to the year 526 B. C. exhibits the true genius and character of sculpture, and has likewise erected the most numerous and the noblest of its monuments. In establishing this principle, we have not been guided by the often fanciful, always deceitful, analogies discoverable in the varying productions of art, but have been directed by the steady operation of the laws and institutions of society, which govern the spirit and tendency of the arts themselves. The second period, from Cambyses to Cleopatra, is mixed in its principles of government as in its arts. Still the master lines of the primitive age were too widely drawn, and too deeply traced to be obliterated or even much obscured. The Persians carried art from, but brought none into Egypt; and had it not been necessary to account for the retrogression under their usurpation, perhaps the second era had with more propriety been commenced with the foundation of Alexandria. The close intercourse with Greece which certainly existed during the whole of this period has been by some attempted to be carried up so high as the reign of Psammeticus; and hence, following up the weak partiality of the Greek historians, Egypt has been denied all claims to originality in the arts. We have already, with due deference, reprobated the absurdity of theorising on the invention of arts, originating in the universal feelings of human nature. But here the genius of Greek and of eastern art are as opposite as light and darkness: granting then the assumption, which people must have been the creditor?—Egypt, not Greece; for if this king lived at the time stated by those who maintain the opinions now opposed, the art of sculpture in particular was in a state of far higher advancement in the former than in the latter country. With the Macedonian conquest then, not earlier, commences the active influence of Grecian taste; which, without changing the grave severity, the solemn majesty of Egyptian art, softened its sternest and most rigid elements; freed, as far as their consecrated usages would permit, its forms from conventional stiffness; and inspired some sparks of life, of grace and of variety. The third and last era has been added in deference to received opinions, but it is connected with the primitive age merely as an imitation with its original.

In Egyptian sculpture, thus properly understood, we find little to excite that admiration in which travellers and enthusiasts in the cause of antiquity have been prone to indulge. Still we do discover some excellent first principles, and occasionally beauty of detail: but both are without rule, and seem the effects rather of chance than of design, or refined perceptions of symmetry. Their best statues have an elevation of seven heads and a half, and are divided into two equal portions—the torso and limbs, at the os pubis; proportions not unpleasing because founded in nature. They show, however, nothing of that characteristic beauty which, in the varied harmony of parts, indicates moral or physical capability. Their figures consequently have nearly all the same character. The proportions, taken more in detail, follow the same principle; yet are often brought out with considerable propriety and softness, but without anatomical knowledge, especially of the internal details, the heads of the bones, the insertions and terminations of the muscles never being correctly indicated. Hence the forms appear coarse and inelegant, the limbs heavy and inert, without vigorous marking on the joints; the deeper depressions only and the strongest projections are aimed at, not feelingly touched. From this want of anatomical precision, being in these more easily concealed, perhaps arises the circumstance, that the female possess more elegance and beauty than the male statues, and with the exception of the hands and feet, which in both are gross and heavy, the nude in the arms, bosom and limbs of the former is often moulded with considerable delicacy both of contour and of finishing. With these deficiencies of science, the Egyptian statues would appear more like *abozzate* than having received the last finish, did they not present two redeeming qualities, ever highly esteemed by a cultivated taste; simplicity of composition and great breadth of parts. These, indeed, united with sharpness of chiseling, may be regarded as the peculiar excellence of Egyptian, compared with ancient art generally, and which place its productions among those of eastern art, without a rival next to the labours of Greece.

In Egyptian statues, it is further to be observed, that the attitude is constantly rectilinear, denoting that state of art when poverty of resource limits its search of the beautiful by the difficulties of execution. It is in fact the first choice of infant invention, rendered permanent by prescriptive institutions. From the curve being thus unknown in the contour, the action is necessarily angular, whenever the movement is not parallel to the gravitating line of the figure. Hence the arms have but two positions, either hanging close to the sides, or crossed at right angles upon the breast; or sometimes varied by one placed in each posture. Lateral motions are likewise unattempted, the statue standing equally poised on both limbs; with the feet not exactly opposite, one more advanced than the other, and often almost in front. In every posture of standing, sitting, or kneeling, these remarks apply: hence it is easy to conceive that little of grace, ease, or animation is ever to be found in the most perfect works: yet we often observe a grave and staid serenity not unpleasing nor devoid of interest.

In the genuine sculptures of Egypt, little of expression or of character is to be found. As in the selection of attitude the artist has been guided, not by the beautiful, but by his own timidity of hand, and confined resources, so in expression, seldom more than a vague and general resemblance of emotion has been attempted; such indeed as might be produced by casually arranging symmetrically the different features. Although heads are very frequently finished with wonderful labour, the effect is always feeble; this arises from the style of art, and peculiar character of visage which appear to have constituted the beau ideal of those ancient masters. The features are flat, the countenance Ethiopian; the first are just sufficiently distinguished to have the effect of separating them, there being no depth of shadow to give contrast and firmness. The eyes, whether long and narrow, as in the earliest era, or more full and open, as in the Greco-Egyptian period, are flat, and almost equal with the general level of the face,—the nose broad and depressed,—the lips thick, though sometimes touched with great softness and delicacy, but always sharp on the outer edges; the cheeks, chin, and ears, large, ill made out, and without feeling. The whole is uniformly surmounted by harsh and disproportioned masses of drapery, which overpower the little effect that would otherwise be produced, and render the expression still weaker. The superior beauty of some of the colossal heads may perhaps be rightly attributed to their being most probably portraits. Conventional art, even in the most skilful hands, is rarely pleasing; nature, though rudely imitated, possesses always a degree of beauty.

Respecting the technicalities of Egyptian statuary, some scattered details are to be found in various of the Greek writers. These hints have evidently misled modern critics, who have applied to the most ancient state of the art, and generally, those refined practices which Diodorus and others described as known in their time, many centuries after Egypt had in some measure become the pupil of Greece. If a conjecture might be hazarded on this subject, it would appear that the Egyptians, in the infancy of their arts, were guided by an outline traced round a human figure, whether dead or alive, placed upon the block, and extended flat upon the back, with the arms close to the ribs, exactly as their statues are composed. This supposition will account for the correctness of the general proportions, which would be thus ascertained from nature. Also we can detect no theory of proportional parts different from what could thus be obtained, while those details which theory would preserve, but which could not be thus measured, are so defective. Of anatomical knowledge, as is evident from their works, they possessed no more than a view of the living form, in its simplest relations, could give. On this subject it is frequently maintained that the Egyptian artists had carefully studied the structure of the inferior animals, as instanced, it is said, in existing specimens; the hypothesis may be true, but certainly the proof adduced is not to be admitted. Less of restriction undoubtedly has been imposed, and more play of imitation allowed in the one case, but equal breadth and correctness of parts, are to be met with in their representations of the human as of the brute form; witness the head and shoulders of the Sphinx, and of the Memnon, compared with the lions of the capitol, and others at Rome, so justly admired as the finest examples in this department.

In fine, when we contemplate Egypt, if not the parent, at least the earliest nurse of art—when we view her advances in improvement previous to the existence of many other ancient nations—when we examine her early monuments—we are struck with wonder and astonishment. But comparing her with herself—the reign of Sesostris with the dynasty of the Ptolemies, a most melancholy falling off from early promise is remarked,—every nation whom she had taught had now outstripped her. Nor is it difficult to trace the cause—convention and prescription, and intellectual tyranny, had assumed uncontrolled empire over her arts. The first principles were bad, because not founded in nature; the imperfect models thus produced, by superstition consecrated and rendered permanent—fixed barriers to improvement. The genius of her institutions was to rest satisfied at a point of the easiest access, and thus in science and in art she was condemned to a hopeless and eternal mediocrity.

Assuming the era of Egyptian art as the first lucid point in the history of ancient knowledge, we remark the rays of intelligence thus concentrated to diverge in opposite directions, eastward over the regions of Southern Asia, and westward over part of Europe. Here in Greece and in Italy, the day spring was hailed by minds who rejoiced in its beams, and lighted up its splendours. But in the numerous and ill explored monuments of Persia and of Hindostan, the vestiges of this early illumination are too few and too faint to enable us, with any degree of accuracy, to determine its progress or extent. This consideration alone, would not however have prevented an attempt, had such an inquiry promised any illustration of the general subject: for whatever might have been the refinement of these countries, their arts, like wandering streams, gradually lessening as they recede from the parent source, must be regarded merely as derivations from those of Egypt, and bringing no increase to the grand tide of improvement. Of Indian, Persian, Babylonian sculpture, therefore, it appears unnecessary to enter upon any investigation. The ruins of Persepolis, for instance, in one palace of which a recent traveller counted upwards of a thousand sculptures, as well as the excavations of Ellora; the obelisks, statues, and tombs on the Ganges, all exhibit a corresponding though less perfect style, and evidently belong to a later age than the similar works of the Thebaid.

These views, indeed, are opposed by names who deservedly rank among the first in English literature, and who support the priority of the arts of India, considering this as the source of Egyptian and of Grecian knowledge. One consideration emboldens us to differ from authorities so respectable. Sir William Jones and Dr. Robertson have brought, in support of their opinion, all that philological and antiquarian erudition could accumulate; but they have failed in examining the subject as artists, and have not been determined in their decision by those principles of judgment which art supplies. Now in this, its only true aspect, the subject presents a very different view. Both the sculpture and architecture of Egypt bear the impress of uniform simplicity, and the same forms are preserved in the earliest and latest monuments. The grand lines of composition are few and simple in the extreme, accessories are sparingly introduced, and bear the same sober, massive, and unpretending character. In the works of Asiatic art, on the contrary, although resembling those of Egypt in their general design, there appears a style of ornament, replete with complicated detail and pretension. Judging, therefore, according to the acknowledged truths of art, these defects in keeping evidently arise from the superinduction of the offending parts upon the severer and simpler master lines of a more primitive composition. Nor can it be replied that in Egypt a refinement of Asiatic taste has occasioned this difference, because this would imply a corresponding superiority in other respects. Now in mere dexterity of hand, the works of this country are more than equalled by those of India. But the Egyptian artist has never advanced beyond his means; he never attempts what is beyond his knowledge or practice; and we evidently observe that his science extended not beyond what is accomplished.

From the peculiar interest of the subject, we might enlarge on the state of art among the Jews; but this would likewise be to deviate from strict order and utility. Much learned conjecture might be quoted, and opinions brought to pass in review, amusing perhaps, but hardly instructive. The Bible, the best authority, informs us that Moses was the most accomplished of his nation, and adds, by way of eminence, that he was skilled in all the learning of the Egyptians. From the same source the arts of his people were derived; they had been the bondmen of Pharaoh, and knowledge was cheaply purchased by temporary slavery. The scriptures every where confirm these views; the molten calf of the wilderness was evidently a symbol of the Egyptian Apis, and would necessarily resemble its prototype in form and workmanship, and points out beyond dispute the character and origin of Jewish art. The descriptions which occur posterior to this in other parts, both of the historical and prophetical books, show that taste was not refined by the lapse of time. Every passage, in fact, proves the reverse, and that art among the Israelites quickly lost the severe and simple grandeur which their residence in Egypt might have fostered. Witness the relievos on the Arch of Titus, the sole vestiges of Jewish art in existence.

SECTION II.

Etruscan Sculpture.

The origin of the ancient inhabitants of Etruria involves a question of more than usual intricacy, even among those historical inquiries where materials are scanty, or if abundant, perplexing and inconsistent. Here both species of difficulty are to be encountered. A few scattered rays only of certain knowledge break through the gloom of time, and the still deeper obscurity accumulated by conjecture and hypothesis. These dispersed lights we shall endeavour to concentrate and to direct steadily on the subject, free from all adventitious shades of theory or opinion, in order that the reader may be enabled to judge of the real influence exerted by this people on the progress of ancient art.

It is universally conceded, with some exceptions as to the extent of their dominion, that the Etruscans or Thyrreneans possessed at an early period the empire of Italy, and much of the refinement of the ancient world. But of their power and of their skill a few imperfect remains alone exist; while their scanty annals have reached us through the medium of the narratives of the Romans their conquerors, or of the Greeks their rivals. Of these relations the writers are divided between two general opinions: one party affirms that the Thyrreneans, assuming the name from their leader, came originally and immediately from Lydia; in opposition, it is asserted that Etruria was first peopled by the wandering tribes of the Pelasgic race who finally and at different times settled in Italy. On these two opinions, or modifications of them, modern authors have erected various, and in many respects conflicting systems into which we do not enter. At the same time, to adopt exclusively either the Eastern or Grecian colonization of the Etruscan states, will neither accord with contemporary, nor explain subsequent events. Under those circumstances, an endeavour to reconcile the discrepancies of statements which doubtless were drawn from purer and more extensive sources than can now be consulted, appears the only advisable proceeding.

Of the Nomadic nations who first inhabited Greece, the Hellenic and Pelasgic races were the most powerful, distinguished by different character and separate descent. The former, conspicuous for attachment to their native soil, made early improvement in the noble attainments which are fostered by settled habits; the latter, of a wandering disposition and uncultivated manners, never became eminent either in Greece or in Italy. But there is undoubted evidence, not denied by any party, that the Etruscans had attained a degree of skill in the arts, opulence, security, and wisdom in their institutions, while the Greeks were yet in a state of pastoral rudeness. Into Etruria, therefore, the most ignorant of the roving tribes of Greece could not introduce that science and refinement unknown in their native country; nor, as distant colonies, is it reasonable to suppose they could have outstripped the parent state, except by union with a more refined people previously occupying the seats into which they were received. On the other hand, the mythology of Etruria is identical with that of Greece, not merely in the general similarity which indicates a common though remote origin, but exhibiting a system adopted in a state of relative perfection. Again, Etruscan monuments commemorate the earliest achievements in Grecian history prior even to the war of Troy, and of which no trace is to be found in the records of Grecian art. These facts point to one only consistent and rational conclusion; namely, that there were two migrations of colonists into Etruria at distant intervals and from distant settlements. This view reconciles the seeming disagreement of the classic authorities. It would appear, then, that the north-western shores of Italy were peopled as early as any part of Europe, and from the same eastern sources. These colonies, attaching themselves to commerce, naturally kept alive or improved whatever of knowledge they previously possessed in peaceful studies, to which the predatory, pastoral, and wandering life of other tribes, though perhaps established at the same time, proved fatal. These original settlers, who arrived directly from the east, appear to have been joined before the time of the Trojan expedition by numerous bands of the wandering Pelasgi. The two nations seem to have gradually coalesced, the warlike habits of the Greeks enabling the Etruscans to subjugate almost the whole of the peninsula, from the confines of Liguria to the straits of Messina; while the refinement of the latter could not fail to effect a favourable change on the character of the former. It was an error very likely to be committed, to date the commencement of the nation from the rise of the empire, and to confound intellectual with political power. The Etruscans would learn from their allies the new and more lovely modifications of older superstitions; and, to a people who had made some progress in the exercises of imagination, powerful charms would be presented, in the early records of Greece, where, to use the expression of Strabo, all is marvellous and tragic land.

Ancient historians of the greatest fidelity and research have praised the wise legislation and equitable government of the Etruscans. The whole of Etruria was separated into twelve divisions, over each of which presided a chief magistrate or Leucomon. From this supreme council of twelve, the members chose a king, or more properly commander-in-chief, who, in war, conducted to the field the united armies of the republic. The election of these governors was vested in the people, and the nation is said to have cherished an almost personal hostility to hereditary kings. The constitution of the Etruscan state thus combined the dignity and union of aristocracy, with the energy and freedom of popular government. It was the former in the executive, the latter in principle. To this admirable polity, to the security which it assured, to the emulation it excited, is chiefly to be attributed the early progress of the Etruscans in art and elegance. A principle is thus ascertained which fully accounts for the superiority of this people, and which furnishes another proof of the influence, insisted upon in the commencement of this essay, that political institutions exercise over the character and productions of national genius. We do not enter, therefore, into farther discussion on the origin of the inhabitants, by exhibiting the various arguments in support of the view we have embraced, which might be deduced from a comparison of ancient authors—from the analogies of the Greek and aboriginal dialects of Italy—from the evident union of the Cadmean with a more decidedly oriental, and consequently more ancient character in the Etrusco-Pelasgic alphabet—from the style, and in some instances, as at Pæstum, the situation of Etruscan architectural remains. It is sufficient for the reader to bear in mind, that sculpture in Etruria had attained a degree of excellence prior to any extensive cultivation of the art in Greece.

The remains of Etruscan sculpture are not numerous, and of these some are of doubtful authenticity. The works of national art, taken in general, consist of coins or medals—statues of bronze and marble—relievos—sculptures—gems—engraved bronze—and paintings.

The coins or medals of the various Etrurian cities are not only the most numerous, but the most ancient remains of their arts. By means of these, many difficult points in the history and geography of ancient Italy have been, or may be explained. As evidence by which to judge of the refinement and skill of these early ages, many are to be regarded as wonderful examples of beautiful design and delicacy of execution. They are of two kinds, either mythological or merely symbolical in their representations, and appear all to have been cast of a composition, not a pure metal. As mistakes are likely to occur from confounding the colonial Greek or Phœnician coins with the genuine Etruscan, no observations should be regarded founded on specimens without inscriptions. The practice of constantly placing inscriptions on their works, seems never to have been omitted by the artists of Tuscany, and furnishes a very probable presumption respecting the authenticity of their labours.

Etruscan statues are either of bronze or marble, each of which classes may be again subdivided according to the magnitude of the works. Of bronze figures in miniature, resemblance both of men and animals, examples are commonly to be met with in museums. These probably are images of the household deities, and not unfrequently seem to have been ornaments merely; but from specimens so minute, it is not easy to deduce any certain or useful conclusions. Of bronze statues the size of life, there are very few, and of these scarcely one has escaped suspicion as to its antiquity. Of the marble statues, whether large or small, it is exceedingly difficult to pronounce whether they be Etruscan or Greek.

Relievos bearing the general character of Etruscan are found in Rome, Florence, and other parts of Italy. Of these works, the most ancient are doubtless sepulchral monuments, erected prior to the practice of cremation, as a mode of sepulture; but we have also sarcophagi belonging to the latest era, when the artists of Etruria may be considered as almost colonial Greeks. Intermediate between these two are various mythological relievos and altars. Of these Winkleman selects as genuine four, now, if we remember aright, in the museum of the capitol. Apotheosis of Isis; a round altar with three figures; a square altar with the labours of Hercules; and another round altar, or rather mouth of a well. To these recent discoveries have made several additions.

Engraving on gems seems to have been brought to some degree of perfection at an early period both in Italy and Greece. Of this minute art, probably the oldest specimen now in existence represents five of the seven chiefs who fought against Thebes. It is a cornelian $7\frac{1}{2}$ tenths by $5\frac{1}{2}$ tenths of an inch in the diagonals of the oval facet on which the figures are engraved, three seated and two standing, each having his name affixed. The composition is extremely inartificial, but not unpleasing, although by no means indicating a refined knowledge. Other Etruscan gems, however, have been found, which equal the most exquisite performances of ancient art,—such as the cornelian representing Tydeus drawing the arrow from his leg; and Peleus dressing his hair, engraved on an agate. These three, and Etruscan gems in general, are of that form called *Scarabei*, from their resemblance to a beetle, being oval, flat on the engraved side, and convex on the back. Each is pierced through the longer diameter, leaving it doubtful whether worn suspended as an amulet from the neck, or on the finger as a ring.

One of the most curious remains of Etruscan art, which is also the most numerous class, comprises engraved bronzes or pateræ. These, it is well known, were round, flat and shallow dishes, from which was poured wine or water during the sacrifices. The Etruscan pateræ are not quite circular, but have a short tapering handle, round which sometimes is brought the shallow brim, so that it forms part of the cup. This handle is peculiar to Etruscan workmanship. On the bottom inside, which is perfectly flat, and from four to six inches in diameter, is engraved in deep, broad, and bold lines, usually some mythological composition. Of these designs the style is simple—the lines few and straight, but exhibiting firmness and correctness of hand: with more of power than grace of expression or attitude. These make a near approach to our outline engravings, except that the strokes have much more force. Indeed we remember to have examined one at Bologna, representing the birth of Minerva, from which the brim had been removed, and being put through a printing press in the usual way, had given off a very good impression exhibited along with the original.

To examine the Etruscan paintings hardly falls under our present limits. With a few imperfect sepulchral remains at Tarquinia, they are to be found only on vases; if, indeed, these latter are not properly to be considered as belonging to the colonial Greek school. For our own part, we are persuaded that not one of the Necro-Etruscan vases, as they are commonly styled, is of a date anterior to the consular government. Funeral ceremonies among the ancient inhabitants of Italy consisted in simple inhumation, and it was not till after their intercourse with Greece that the burning of the body, and the consequent use of urns were introduced. True, vases of magnificent design and large capacity, appear to have been consecrated in temples, and employed as ornaments in houses; but granting some of these to have reached our time, the nature of the subjects represented, or the style of the design, shows that they cannot be of a higher antiquity than the date assigned. Regarded as works of art, these productions can hardly be admired sufficiently. The pictorial representations are of two kinds, monochromatic shadows, usually black upon a light ground, or monochromatic outlines in similar style; or the order is reversed, the ground being dark, the figures light, but whole pieces are never executed after this method. Of these two manners, the outline figures present the more perfect specimens of design, and when the difficulty of tracing an outline at a single stroke in a pigment which admitted of no repetition, and on a surface from which no line once impressed could be effaced—we compare the correctness, truth, beauty, grace of the forms and expression, we are forced to ascribe no ordinary skill and dexterity to the artist, and no common taste and refinement to the age and nation in which such works could be produced. One general observation, however, may be recorded; taking these remains universally, the delineations are inferior to the perceptions of the abstract beauty of forms, perceivable in the shape of the vases themselves; whence perhaps the conclusion may be ventured, that the Etruscans were greater in sculpture than in painting. These observations do not invalidate the high antiquity of Greek vases.

From the spirit of some of the preceding remarks, it might be inferred that little certainty can be obtained in this inquiry; that much doubt, difficulty, and obscurity is involved in the history of Etruscan sculpture, no one who has studied the subject will deny. But it is equally true, that these doubts and difficulties arise as much from the absurd opinions and interminable wanderings of those who have pretended to elucidate matters, as from any erroneous principles in the real grounds of judgment. Writers have ventured upon this theme, which requires both taste and knowledge of practical art, who were mere antiquarians; what is even worse, each has his favourite theory to make good. Laying aside all prepossessions, therefore, and with some experience in the application of those principles on which works of art are to be discriminated, we shall find, not only that there is a certain and definite style which peculiarly distinguishes Etruscan design, but also that the remaining labours of this school may be regularly classed, from the degree or kind of excellence which they exhibit.

Art contains within itself, and, if rightly interrogated, will always furnish precepts by which its own productions may be discriminated. In searching for these principles, we must carefully compare the monuments of different nations and those of the same people with each other. We shall thus be able to detect certain peculiarities of mode—of expression—of form—certain specialities in the relation between fancy and feeling and nature, which constitute what is termed a national style, or, in other words, characterize the national genius. Thus, if we place in contrast certain sculptures found in Italy with others of any age from Greece, there will be perceived considerable diversity in the relations just mentioned, clearly indicating a mental as well as mechanical diversity. These remains, history informs us, can be ascribed only to the early inhabitants of Etruria, and to this diversity is given the name of the Etruscan style. Again, compared among themselves, these remains exhibit intrinsic distinctions of manner or excellence, which enable the examinator to assign them to their respective ages. We thus discover three epochs of art among the Etruscans.

The first or ancient style commences with the origin of the people. It has been assimilated to the Egyptian, but the resemblance is not more than that general similarity which characterizes the infancy of invention in every nation. Yet there are distinctions to be traced which clearly discriminate the two manners. In the earliest monuments of Tuscany may be perceived an unfettered imagination essaying its powers in modes feeble indeed, but varied;—no systematic, as in eastern art, no conventional representation. In Egyptian sculpture every thing seems to spring from a foreign impulse, whose object is not the advancement of art, or the imitation of nature;—in Italian statuary, all wears the impress of native volition. The characteristics of the first epoch are rigidity—ignorance of the naked—feebleness of relief—perceptions of beauty, especially in the forms of the head, exceedingly imperfect. The contours are composed nearly of straight lines, the limbs are without joints, and the action forced, yet destitute of movement. The face is an imperfect oval, elongated at the base, and ending in a peak. The eyes, long and narrow, are placed oblique; as is likewise the mouth, the external angles in both being drawn downwards. The features are flat; and here the meagreness of relief is chiefly apparent, the eye-balls being nearly on a level with the frontal bone. The general effect thus remains without power, while the individual forms are far from pleasing. Yet there is frequently a robustness of design, a vigour and firmness of handling, which, though destitute of grace, seem to contain the rudiments of those forcible, masculine, even exaggerated conceptions and execution, the peculiar characteristics of Tuscan art in every succeeding age.

The style of the second epoch marks these characteristics in their full display: the former feebleness begins to disappear; and in the few remaining examples, though we cannot trace improvement in all its stages, it may be ascertained that melioration commenced by adding boldness to the relief. The cause of this it is perhaps easy to discover in the practice of engraving on precious stones, to which the artists of Etruria were attached from an early period. These works being executed, as they now are, by means of a wheel, depth of depression could be easily made on the ground, while the figures were thus more fully relieved. Observing the powerful effect obtained, the application of the improvement to works of sculpture generally was obvious. But by such a style of execution, the former defects in design would be rendered only the more apparent. Hence would quickly follow improvement in the forms, in the study of nature, and in truth of expression. It is difficult in art, as in every human pursuit, to preserve the just mean. The Tuscans carried to an extreme the discovery which had conducted to bolder practice. All soon becomes forced, violent, and exaggerated. The action is constrained, the movement unnatural; the whole aim is effect, and to this every feeling of truth or of simplicity is sacrificed. The proportions are robust beyond those of nature; the muscles are constantly in action, and the retiring curves are so deeply impressed, that breadth of parts is every where cut up by alternate ridges and hollows. The bones are learnedly, but so strongly pronounced, as to render the whole effect harsh, dry, and mannered. A want of character is the necessary consequence; for the forced and violent in art always proceed from inability to express the workings of the mind in any other manner than by their most sensible and least intellectual signs. The Etruscan style of sculpture is in fact similar to their architecture. There is strength, and massiveness and power; there is also vigour of conception, and play of execution: but there is wanting delicacy of proportion, nice discrimination of character, and all the pleasing propriety and repose of the sweet and gracious in art.

The genuine style of sculpture among the ancient Etrurians belongs to the second epoch. In examining its characteristics, we can hardly persuade ourselves that these are not derived from the works produced in the same country during the fifteenth and sixteenth centuries. The analogy observable in the national genius at such a distance of time, and after so many vicissitudes, moral, intellectual, and political, is remarkable, and may hereafter demand our notice.

The third epoch embraces that period which marked the gradual disappearance of the Etruscans from among the nations of Italy. Their political empire merged in the rising dominion of the Romans; the discriminative character of their genius was lost in the arts of the colonial Greeks. In the monuments of this era, the ancient style is still to be distinguished; for though the Italians now become imitators of the past, and rivals of the living Greeks, yet the national style was never entirely abandoned. During the early portion of this division many excellent works appear to have been executed, and to these the Latin poets and historians seem to refer. Judging from the most perfect remains, the proportions were rendered more light and graceful, the forms and expression of the heads more beautiful, the execution was softened indeed yet still retained a degree of exaggeration and harshness. The melioration was temporary; and perhaps it is not fancy alone which discerns, in the successions of subsequent feebleness, the gradual approaches of political depression.

In regard to the dates and duration of these divisions in the history of art, they seem nearly to have coincided with as many revolutions in the political annals of the nation. From a small state on the north-west coast, the Etruscan gradually extended its empire from sea to sea, and from one extremity of Italy to the other. This the era of their greatest dominion corresponded with the infancy of their arts, or at least with their first degree of refinement. By the expulsion or conquest of the Siculi, this complete subjugation of the Peninsula appears to have been effected about 80 years before the Trojan war. The Etruscan dominions then consisted of three portions, Etruria Circumpadana, Media, to which properly belong the name, and Campania. The last, containing the whole of the country south of the Tiber, was neither a secure nor a permanent conquest. The Dorians who landed in Italy about 130 years before the taking of Troy, together with the ancient inhabitants, attacked and gradually reduced the Etruscan power on this side. The Etruscan medals, however, which are found in all the remotest parts of the present kingdom of Naples, attest the ancient dominion of that nation. In this southern portion of their empire the Etruscan first mingled their arts with those of Greece. To this union we ascribe the excellence of the sculptors of Magna Grecia, when, at a period long subsequent, the schools of Rhegium and Crotona supplied masters superior to those of the mother country. The Greeks rapidly improved, but discovered slowly. The progress already made by the Etruscan, was therefore early appreciated by the Dorian colonists of southern Italy; a foundation was thus obtained on which the fervent genius of the latter quickly raised a superstructure of beauty and excellence surpassing any example in the parent state. In the first era of their art then, the advantages were imparted, not received by the Etruscans.

On the north the Etruscans had continually to combat against the Ligurians and Gauls. By those persevering enemies that division of their empire called Circumpadana was at length reduced. The coins, however, still found along the shores of the Adriatic, bear witness to the arts and sciences of Etruria. We thus arrive at the second epoch in the political history of this interesting people, when shut up within the boundaries of Etruria Media, their ancient seat, and where their admirable polity was best organized, they enjoyed freedom and security. This era, which corresponds not with their political grandeur, coincides with their greatest and most original acquirements in the arts. This was the reign of their second style, bold, masculine, and energetic, it was calculated to awe and astonish, rather than to sooth or delight the mind. Their architecture partook of the same character as their sculpture. The order, which still bears their name, sufficiently evinces the massive and powerful structures which it was destined to adorn or sustain. The noblest of all architectural inventions, the Grecian Doric, has been derived from this source. Even yet in modern Tuscany, the traces of her ancient inhabitants remain, like those gigantic skeletons of animals described by naturalists, but no longer existing among the orders of life, and which nature created in her primeval strength.

While each of the twelve capitals of Etruria was a school of art—at once the rival and the friend of her compeers—each exciting the industry and directing the advance of the other—each the Athens of ancient Italy; Rome, animated by the brutal spirit of military conquest, broke in upon these intellectual and refined labours. But force was no match for science; the Romans suffered severely from the first effects of their temerity. The opportunity, however, of crushing the growing pest was allowed to pass away; and Etruria, with her free institutions, her elective magistracy, her solemn insignia, fell beneath the rude despotism of Rome.

Thus terminated, 480 years after the foundation of Rome, the second era of Tuscan art. For some time afterwards indeed, we may discover that sculpture was practised to considerable extent. But it soon ceased to be marked by national character. The Roman dominion now embraced the circuit of Italy, and all former distinctions were lost. The Greek colonist, and the Tuscan freeman was alike the vassal of Rome From this period we again trace the union of the arts of the two nations, and Greece now repaid what she formerly borrowed, for soon after the reduction of the Etruscan republics, we conceive the finest specimens of their sculpture now remaining to have been produced. But their common masters did not foster the arts as internal and native ornaments of their empire, although they could place a meretricious value upon them, as the spoils of war, as the prize of the captor.

the evidence of conquest. Under this ungenial patronage the ancient arts of Ausonia soon ceased to flourish, and became as if they had never been.

We might now proceed to class, according to their respective dates, the monuments remaining of these interesting periods. But without engravings of the various subjects, we despair of rendering the descriptions interesting, or even intelligible to the reader. Generally then, we consider the bronze remains as the most ancient, though not more authentic than the marble sculptures, where these display intrinsic evidences of the Tuscan style. All arguments against the antiquity and genuineness of the latter drawn from the nature of the marble, on which so much stress has lately been laid, we regard at least as extremely suspicious. We would attribute the manufacture of the exquisite fictile vases, called Etruscan, chiefly to the period intervening between the expulsion of the Etruscans from southern Italy, and their subjection by the Romans—that is, to the second epoch of their arts and empire. Also these vases we believe to have been fabricated by the Greek colonists only; and it is known that in some places they formed subjects of a lucrative commerce. As a proof of this origin, vases have been found throughout the whole extent of lower Italy and Sicily, but very few have at any time been discovered in upper Italy. Finally, that no exaggerated importance has been attached to the arts of the ancient Etruscans, will be sufficiently apparent from one of many facts; when the Romans captured Volsinum, one of the twelve capitals of Etruria, they carried away two thousand statues from that city alone.

SECTION III.

Grecian Sculpture.

The history of sculpture in Greece naturally divides into two branches of distinct inquiry. We prefer commencing with the chronology, masters, and labours of the successive schools; the second branch will embrace the consideration of the principles and theory of the beautiful as conceived by the Greek artists. This arrangement, although differing from the methods usually followed, seems to promise facility and directness of inference, with a consequent veracity of judgment.

The imagination approaches the subject of Grecian literature, or of Grecian art, with something like to sacred enthusiasm. The mind anticipates the delight of unfolding, amid examples of perfection, the advances of taste and the march of genius. But, alas! the splendour with which the general subject is invested, is often but the reflection of brightness that has passed away—filling the thoughts with light and beauty, yet leaving few memorials of its progress or its authors. Of those whose conceptions peopled the cities and temples of their country with a silent, yet breathing population of matchless forms, a few names alone subsist. From the casual pages dedicated to this narrative, we turn in sorrow, not unmixed with indignation, to the ample relations of war and bloodshed, of crime and misery, which history has so lavishly bequeathed. Is human nature then, really so degraded as to take pleasure in preserving only the mementos of its own depravity; or is good, but an episode in the drama of human existence, to be hurried over as staying the main action? Have the reigns of amity and wisdom been so brief, so far between, that the picture of the past is but as one mighty battle piece—where every figure is agitated with fury or convulsed with agony—where every arm is raised to strike or ward—where every eye flashes with hate, or closes in death? Perhaps it is thus ordered more deeply—more affectingly to impress the truth—that there is no volume, save one alone, whose pages tell of unmingled love and peace and purity and holiness.

In arriving among the arts in Greece, although the records be so imperfect—so inadequate to the interest of the subject,—we do, however, escape from barbarism, and in some measure from uncertainty. It is like revisiting the gracious aspect of heaven from wandering amid the hideous and undefined forms of darkness. We possess the personal narrative of Pausanias, whose "I saw," or "which is still to be seen," coupled with the description of the noblest monuments of human art, excites the vain but excusable regret of the modern reader. The 35th, and 36th chapters of Pliny present an elegant compendium, evidently drawn from the best sources—not unfrequently indeed from the writings of those very artists, by whose hands had been executed the masterpieces described. The poets, orators, and philosophers, afford many remarkable notices, and speak with kindred sympathies of kindred labours.

In arranging these precious bequests, we shall adopt a threefold division of the ages whose relics they embalm. The first period will extend from the rude beginnings of sculpture in Greece to the artists immediately preceding Phidias. The second comprehends an interval of about 150 years, from Pericles to the death of Alexander. The third embraces those evil days from that conqueror till genius expired in the country of Homer.

These divisions mark intrinsic revolutions in the progress of art. The first exhibits the rise and perfection of material art, in which form, not intelligence, constituted beauty. The second—a glorious but brief period, displays art in its highest sublimity, when over surpassing and faultless symmetry, was breathed the expression of intellectual energy and nobleness. The third, like the last age of man, is decline, feebleness, and death.

First period.

The imagination of Greece was poetry from the beginning. Her consecrated groves—her haunted streams—her flowery plains—the depths of her azure mountains, were constituted at once the residence and the representatives of her earliest divinities, heroes, and benefactors. The alliance of natural objects with the human heart, as shadowing forth its affections, or as signs of its regrets, is the origin of all exalted art, as it is the purest species of Polytheism. As such a system indicates only the existence, not the presence, far less the form of a deity or departed worthy, it would be cherished only by a people simple in their habits, and ardent in their feelings. Accordingly we discover permanent traces of this simplest and purest superstition solely among the sunny vales and golden isles of Greece; for this her earliest faith has deeply tinctured much of what is most exquisitely descriptive or sentimental in her poetry.

But a belief so refined and untangible in its forms—so remotely addressed to the senses, would prove insufficient to maintain an empire over the mind. Men therefore would speedily attempt some method of representing the immediate presence of the objects of their veneration or worship. Their desires in this respect, however, would necessarily be limited by their knowledge. In these primitive ages, objects, rude and unfashioned, would suffice to represent the subject of adoration. Nor is this conjecture, or merely plausible hypothesis. Pausanias states that the ancient divinities of Greece were represented by stones and trunks of trees, unformed by art, and that in his time many of these very stones were preserved in temples, and regarded with great reverence. In the time of Adrian, blocks of stone, formerly the objects of ancient worship, as Apollo, Juno, and Bacchus, were to be seen at Thebes, Argos, Delphi; and the Cupid of Praxiteles—the most famous representative of the god of soft desire, was by Phryne, his fairest votary, transmitted to Thespia, in order to replace a stone, adored there from the earliest ages. These and many similar instances have not escaped the notice of some of the Christian fathers.

These were symbols rather than natural representation; but they suggested the first step towards more refined smilitude. As skill improved, the Greeks would attempt to give some regularity of form to these signs. Accordingly the next stage in the progress of improvement was to hew the former blocks into square columnar shapes. Erecting these upon one end, by slow gradations, the artist learned to fashion them into something like a rude outline of the human figure. The extremities, however, seem not to have been attempted, nor were the arms separated from the body, the foldings of the drapery being stiffly marked in deep lines upon the surface. Such, with various degrees, no doubt, of individual merit, appears to have been the state of the art in Greece, when Dædalus, the first sculptor whose name is fully recorded, arrived in that country.

The Greek colonies planted in Ionia, and in the isles of the Egean, quickly surpassed the mother country in wealth and refinement. Of these early establishments, that which first attained to the happiness and consequent power of settled government was the Dorian colony in Crete. We have Plato's authority that the laws promulgated by Minos were not only the most ancient, but the wisest of contemporary systems; this sentiment is fully corroborated by the testimony of tradition, that the gods were born in Crete, and gave laws to the people. Insular situation and maritime power gave security against foreign invasion; a direct intercourse with Egypt introduced the learning and arts of that country; while external advantages were secured and improved by equitable institutions at home.

The opulence, wisdom, and refinement by which the Cretans were thus pre-eminently distinguished, did not escape the notice of the Athenian hero Theseus, when he visited the court of the second Minos, twelve centuries before Christ. Nor were the causes of these effects unappreciated. On his accession to the throne of Attica, Theseus introduced into his own kingdom the improvements he had admired in Crete. While he gave to his subjects a system of regular policy, the arts of elegance which humanize the manners, and then added dignity to religion, the firmest cement of social order, would not be neglected. Accordingly we are to place the hospitable reception of Dædalus in Athens at the time of the voyage of Theseus. Nor can we admit the doubts attempted to be thrown upon the existence of this artist, unless we resolve at once to reject the evidence of classic writers.

The foundation of the first school of sculpture at Athens, destined long after to carry the art to its utmost grandeur, is thus ascertained, about 1234 years before the present era. It is not, however, to be supposed with some, that Dædalus first introduced sculpture into Greece, or even into Attica, but simply that he was the earliest master who instituted something like a school of art, and whose works were long preserved as worthy of notice. We have already remarked, on the futility of arrogating exclusive discovery in arts which owe their birth to the natural desires of the heart; while in the present instance the bare capability of appreciating the improved style of the Cretan, necessarily implies a certain degree of knowledge and of taste previously existing among the Athenians, and corroborating the views above recorded.

The performances of Dædalus were chiefly in wood. Pausanias, who writes in the end of the second century of the Christian era, enumerates not fewer than nine of these labours, the majority of which he had seen and examined. Notwithstanding the injuries of fourteen centuries, and the imperfection of early taste, these works, and particularly a statue of Hercules at Thebes, are described as possessing something of divine expression. Diodorus enters more into detail, whence it appears that Dædalus improved upon ancient art, so as to give vivacity to the attitude by separating the limbs, and raising the arm in varied position from the flanks; as also to infuse more animated expression into the countenance by opening the eyes, which before were narrow and blinking. We mention these particulars for two reasons; they prove the existence of anterior art, and because the passage has commonly been misinterpreted, as if referring to the works of Dædalus, not to those of his predecessors. This sculptor did not confine his talents to one exercise only; he excelled in architecture, and being skilled in mechanics, appears by ingenious contrivances to have given motion to certain of his figures, as in a dance preserved in copy at Gnossus, described by Homer, and reported by tradition to have been a present to Ariadne. This, without having recourse to the absurd notion of Aristotle about quicksilver, may explain the fables which have been united with the story of his adventurous life.

Contemporary with, or more probably anterior to the preceding, was Dibutades. In the humble occupation of a potter at Sicyon, this man became the accidental possessor of an invention the most important to art, both in its immediate and subsequent effects. This was the coroplastic art, or the application of soft materials to modelling the representations of sculpture. It was so named from *Cora*—the daughter of Dibutades, who, inspired by love, traced upon the wall, by means of a lamp, the shadowed profile of a favourite youth, as he slept; that in gazing upon this imperfect resemblance, she might solace the hours of absence. Struck with the likeness exhibited in this sketch, her father carefully filled up the lines with clay, and thus formed a medallion, which, hardened by fire, was long preserved in Corinth as a most interesting relic. To this pleasing incident the poets have attributed the discovery of painting—another proof of the exquisite taste, and of the delightful charm which, to their poetry,—their arts,—their philosophy even, the Greeks have imparted, by the constant union of sentiment with imagination—of the heart with the understanding.

Contemporary, but not pupil of Dædalus, was Smilis of Ægina, famous by his statues of Juno at Argos and at Samos. Working independently, his style differed from that of the Athenian school, while it embraced its improvements. Subsequent to the above, or at least prior to the age of Homer, were Endæus of Athens, celebrated for three several statues of Minerva; Icmulius praised in the Odyssey, as having sculptured the throne of Penelope; Epeus immortalized as the fabricator of the Trojan horse, whose works both Plato and Pausanias mention; Alexanor, son of the "divine Machaon;" with many others, who must have contributed to works enumerated during the heroic ages, several of whose names might be recovered from ancient authors, but whose works had perished or been forgotten.

During these ages, however, it does not appear that sculpture can be said to have progressed farther than that it was not unpractised. And although Athens was thus distinguished in the outset, yet, for several centuries, neither in Attica nor even in continental Greece, was the art nationally cultivated. Almost to the commencement of the sixth century before Christ, the mother country was dependent chiefly on the casual or invited arrivals of artists from Ionia and the islands. From whatever cause assembled, and not unfrequently they were driven from their native soil by political revolutions, ever the enemy of peaceful studies, these sculptors naturally selected as their abode the commercial cities. Here power secured protection, as riches and luxury afforded reward and employment.

From these external circumstances, more than any peculiar predilection or superior refinement in their citizens, we find three schools of art early established in Sicyon, in Corinth, and in Ægina. Sicyon, with its little territory situate upon the south-eastern coast of the Corinthian gulf, though acceding to the equitable jurisdiction of the Achæan confederacy, had long been regarded as an independent and valuable member—a claim which the opulence, intelligence, and commercial enterprise of her citizens amply supported. The situation of Corinth seemed purposed by nature for the seat of arts, empire, and commerce; commanding the navigation of both seas which wash either shore, her position united by land the two grand divisions of Greece. She would have been the greatest, had she not first become the wealthiest of the Grecian states. The little island, or rather rock of Ægina, rising above the waves of the Saronic gulf, nearly opposite Athens, of which it was a formidable rival, affords a striking illustration of the effects of commercial wisdom. By this, a state, insignificant in itself, was enabled to cover the sea with a navy, and to cherish the arts, especially sculpture, in a school if not the earliest, certainly longest distinguished by originality of style and principles. To these primitive schools, or rather seats of art, we might add a fourth, comprehending Chios, Samos, and other islands. These, however, as already observed, were the nurseries from which the preceding were supplied, and merged afterwards into the school of Ionia.

To one or other of these schools belonged those artists, who, in the ages subsequent to the Trojan war, kept alive, without much refining, the knowledge transmitted by Dædalus, Dibutades, and Smilis. From the same schools afterwards arose those masters, who, in the 7th, 6th, and 5th centuries before our era, produced works not without admirers in the most refined ages that followed. Of this latter class, we shall proceed to enumerate in order the principal names, without attempting to reduce them into schools, as from such attempts many contradictions have been introduced into this period.

Rhœcus, the first of this series whose name is recorded, appears, from the testimony of Pliny and concurrent events, to have lived about the first olympiad, or 777 B. C. He was a native of Samos, the inventor of modelling properly so termed, and the first who practised his art in brass. For these reasons, rather than as meritorious artists, have the names of Rhœcus, Telecles, and Theodorus his son and grandson, founders of the Samian school, been preserved. Bas reliefs, their workmanship, in gold, brass, ivory, and wood, were extant in the time of Pausanias, exhibiting the hard and dry manner of Egypt, where probably they had studied. Unless, however, Pliny has mistaken the date, which we here see no reason to suspect, the finishing of the last was very beautiful, since he engraved the emerald, afterwards so celebrated as the ring of Polycrates, and the silver patera dedicated by Crœsus to the Delphian Apollo. Great minuteness and delicacy of finish, the effect of painstaking labour, are by no means incompatible with a state of art, rude in other respects; an observation which seems to have escaped modern authors, and in this particular instance the unobservance has led some unjustly to reject the narrative of the Roman.

In the Chian school we first hear of bronze statues, which, from the durability of the material, were rapidly adopted and multiplied over Greece. These early works, however, are not to be supposed to have been cast; they were executed with the hammer, in the same manner as may still be seen in Etruscan specimens of different cabinets. There were, indeed, two manners; the earlier, and that which continued to be practised in large figures, consisted in joining the parts of them in laminæ or plates, the interior being probably filled with clay; in the second method, used in small statues, the several parts were united in a solid state, most likely brought nearly into shape, and the whole then finished by chiseling, or rather engraving. In both cases the separate portions were at first joined by means of rivets, afterwards by soldering. This latter invention has been assigned to various authors; and after much dispute still remains to be claimed. The matter is intrinsically of slight moment, nor are we disposed to admit the authority of those who talk, of soldering with tin or *iron;* in fact, artists who could form a statue of bronze, would not long remain ignorant of so simple an operation, the utility of which was hourly recurring.

Gitiades, native of Sparta, but a pupil of Sicyon, exercised his profession with success, before the first Messenian war, consequently before the 2d year of the 14th olympiad, or 720 B. C. When Pausanias visited Lacedemon, many of his performances in statues of bronze, were remaining in that city. Statuary, architect, and poet, Gitiades united in his own person all the arts, and in so far may be styled the Michael Angelo of those remote ages.

About the twenty-seventh olympiad, and for nearly forty years afterwards, lived Dionysius of Rhegium, and Glaucus of Chios, carefully to be distinguished from their namesakes of Argos. They were employed chiefly upon the numerous bronze statues placed in the sacred groves of Olympia by Anaxiles, the generous entertainer of the heroic Aristomenes and his people, after the disastrous termination of the second Messenian war. Glaucus is reported to have displayed superior talents, and to have introduced various improvements, especially a better method of uniting the parts of cast figures: but the fame of his contemporary is remembered in preference, as the first who composed a statue of Homer. This identical figure, together with one of Hesiod also by Dionysius, was long afterwards recognised by Pausanias. Hence it is manifest that the world has never possessed a genuine resemblance of the venerable father of verse. Pliny considered the numerous busts extant in his time as ideal portraits, in which, though a certain common air and expression were preserved, the character only, acccording to the conceptions of the sculptor, not the individual features, were delineated. From the general tenor of the passage just referred to in the Greek historian, it would appear that he inclined to believe the bronze, now mentioned, the original whence the primitive idea in all had been taken. This is further apparent from the fact, that he was able to identify the portraiture in its rudest stage. How interesting in this case to compare those sublime heads of the bard executed in the best ages of the art, with the feeble imaginings of the sculptor of Rhegium! To trace not merely the progress of improvement, but to mark the successive acquisitions of genius consecrated to enshrine its own loftiest conceptions of its most gifted possessor.

About this time also must have been sculptured the golden statue of Cypselus, the second of the three in the history of art; and on the dedication of which in the temple of Olympian Jove, the Elians were, by the resentment of the Corinthians, for ever excluded from the Isthmean games. About the twenty-ninth olympiad likewise must have flourished Aristocles of Crete, since before the Messenian exiles had given to Zancle in Sicily its modern appellation, this artist had executed at Elis a group of Hercules combating an amazon on horseback. The attempting and consummation of such a work as this indicates an advanced state, both of invention and of mechanical skill. So early, therefore, as 650 years before Christianity, sculpture must have been understood so as universally to be practised in its most important and useful inventions. In corroboration of this general conclusion additional particulars might be adduced, but sufficient has been done for the continuity of the narrative; in confirmation we may just glance at the contemporaneous condition of the sister art.

Painting, according to Aristotle, was introduced into Greece, for so we conceive the word invented ought to be understood, by Euchirus the relation and ancestor of Dædalus. The first paintings most probably were monochronous, without internal lines of any kind. Hyginon and Dymas were among the last who practised this kind of art; Charamides "first distinguished the male from the female form," according to Pliny; and from the same author we learn that Eumæus, an Athenian, first attempted the representation of every object; which expression, though a little dark, seems from the context to imply, that by this artist human and other figures were first grouped in the same piece. To Philocles, an Egyptian, or to Cleanthes, a Corinthian, is ascribed the introduction of simple outlines circumscribing the object. The discovery was improved by Telephanes the Sicyonian, and Ardices of Corinth; who further extended these simple contours so as to express the natural forms and markings of the parts, movements of the limbs, and foldings of the drapery. Improvement was thus advancing slowly but securely; nothing was yet to be unlearned; the next step, throwing in the lights and shadows, so as to give projection and relief, appeared obvious. Unfortunately, however, Cleophantes directed imitation into a wrong course, by filling up the outlines with different colours laid in flat. This must have greatly retarded the advances of future melioration, as the practice, by suppressing all internal detail, almost threw the art back to monochromatic representation; also it is more tedious to retrace wanderings than to push forward even through obstacles. Hence, though we perceive that in painting, the Greeks had discovered some good principles earlier than in sculpture, we do not find that, in the former, they had actually realized greater improvement in general. At the period indeed of which we now treat, there was a striking similarity in the character and condition of the respective arts. Objects both in painting and in sculpture were represented in a manner infinitely tedious, dry, and minute; while the defects of the composition as a whole were but ill atoned for, by elaborate rendering of the parts, and by the most scrupulous and even wonderful finishing. The encomiums bestowed by Pliny upon the pictures of Elotas and Bularchus, both of whom were anterior to the twenty-fifth olympiad, and consequently contemporaries of some of the sculptors mentioned above, would at first induce the belief, and actually have been brought forward as proofs of the superior excellence of ancient painting. It seems, however, not to have occurred to those who maintain this opinion, that Pliny is thus made to contradict himself; and also that in praising the paintings of Elotas at Lanuvium, which were carried off by Nero, he speaks of their comparative not of their absolute beauty. The battle of Magnete, painted by Bularchus, and which Candaules king of Lydia purchased for its weight in gold, may prove the "fame" in the words of the author just quoted, but certainly not the "perfection" of the art. As the masterpiece of its own age, the picture might be highly and justly prized, while, from the laborious minuteness of its details, the price might not be more than a compensation for the time bestowed.

This passion for extreme finish may be remarked in every remaining work of the age; of which very ancient colossal busts in the British museum are proofs. The taste was introduced and maintained by the limited resources of sculpture itself, by mediocrity in the artist, and by the nature of the ornaments and draperies of the time. Before the fiftieth olympiad, the Greeks always appeared abroad armed; at the public games they assisted naked: but in the retirement of domestic life they were clothed in light stuffs of linen, cotton, or wool. These robes were ample, and naturally fell in numerous parallel rectilinear folds, while they were further arranged symmetrically so as to form a series of triangular plaits one above the other along the margin. Such were the ordinary vestments also of the priests and females which were closely imitated by artists, and thus was cherished as it had been introduced, a style of sculpture, dry, meagre, and laborious.

The school of Sicyon, nearly 600 years before the modern æra, was illustrated by Dipænus and Scyllis, the most famous of her early masters. They were brothers, natives of Crete, and renowned no less by their own works, than for the eminence of their pupils, circumstances which, together with her priority in the pursuit, acquired for the city of their adopted residence the venerable appellation of mother of the arts. The benefits of protection and favourable estimation were thus mutual. On some account, however, the sculptors either retired in resentment or were banished, but speedily recalled, in obedience to the commands of the Pythian oracle. The manner of their return is remarkable, as furnishing an early proof of the operation of a cause, mainly contributing to the final perfection of art in Greece, namely, the respect and importance attached to the profession. The works of the brothers were executed in various materials, metal, wood, ivory, and marble, or of a compound of these, by inlaying, laminating, and joining. Of these different methods, specimens were to be seen in the time of Pausanias, who states also that they sculptured the famous Lydian Minerva, four cubits, or six feet high, out of one entire emerald, and which was extant at Constantinople in the eleventh century. But the fame of Dipænus and Scyllis, as exerting a leading influence on the progress of improvement, rests upon their having been chiefly instrumental in applying marble to the purposes of sculpture; of all substances yet discovered, the fittest for the representations of this art. In Parian marble, statues by these masters, of Juno, Minerva, with others of the lesser deities, were admired in the time of Pliny, excited the cupidity of Nero, and are subsequently described by one of the Christian fathers from the great veneration in which they were held. In proportion, however, as these artists excelled their predecessors in genius, in an equal degree did they refine upon that excess of finish which we have mentioned as giving a meagre and studied effect to the labours of this age. The hair arranged in undulating locks or spiral curls, was laboured as if to be numbered; the drapery disposed in the most rigid and methodical forms, is elaborated with painful minuteness, while the limbs and countenance still retain a tasteless character and expression. Yet they did introduce very considerable melioration; their execution is much more masterly, and the general effect more powerful, as may be seen in the colossal heads of Hercules and Apollo in the British Museum, most certainly works of their school, most probably of their own hands. Of the Sicyonian academy, the most celebrated members were Learchus of Rhegium, to whom is erroneously assigned a statue in metal of Jupiter at Sparta, the separate pieces of which were united by dovetails, being esteemed the most ancient bronze in Greece. Theocles, Dontas, Dorycli des, with his brother Medon, Lacedemonians; Tecteus and Angelion, authors of a statue of Apollo at Delos, the remains of which, with a remarkable inscription, were supposed to be discovered in the 17th century. The latest and most celebrated of this school were Emilius, and more remotely as a scholar Callon of Egina.

Of any single monument executed during those early ages which have yet been particularly noticed, the greatest undoubtedly was the throne or shrine of the Amyclean Apollo in white marble, by Bathycles of Ionian Magnesia. The statue itself was of iron, thirty cubits high, exhibiting every evidence of a style contemporary with, or even earlier than the age of Dædalus. Indeed, as described, with head, hands, and feet only, the trunk being a square pillar, it appears to have been intermediate between a sign and a representation; thus furnishing another proof in support of the remarks introductory to the present section. To support a figure of such dimensions, and also as its base contained the tomb of Hyacinthus, this throne must have been of vast magnitude. It was completely covered with relievos, and adorned with numerous statues, representing incidents of history and fable, either allusive to the story of the youth interred within, or selected as appropriate subjects of agreeable ornament. Among these latter were various scenes from the immortal verses of Homer, an evidence, as has been remarked, that these poems must have been known to the Spartans long before they were first collected at Athens. All the other statues, altars, and ornaments, within the sacred precincts of the temple at Amyclæ, were also the labours of Bathycles, whose greatest work exhibits a singular analogy in the fate of Grecian and of modern art; for by relievos of a kind nearly similar were the reviving powers of sculpture in the fourteenth century exercised.

Bupalus and Anthermus, or Anthemis, brothers, of the isle of Chios, 517 years before Christ, were descendants from a family of celebrated artists, in which, according to Pliny, sculpture had been carried up uninterruptedly from the institution of the Olympiads. Their great-grandfather, Malas, about the 30th olympiad, or 649 before Christ, claims to be the first who applied to his art the beautiful marbles of his native island. Michiades inherited and improved the science of his father, transmitting the accumulated experience of two generations to his own son Anthermus, the parent of those now mentioned. Part of this account may appear discordant with the statement above, that marble was first generally used in the school of Sicyon. Controversy on this subject might easily have been avoided by reconciling the facts. The islands, and Chios in particular, abound in excellent marble; the sculptors of the insular-Ionian school, would naturally have early recourse to this material: while their pupils at Sicyon might rightly enjoy the merit of introducing the discovery into continental Greece.

Be this as it may, and by no other means, can the difficulty be obviated with justice to all parties, Bupalus and Anthermus certainly first brought sculpture in marble to a degree of perfection. The beauty of their works excited the refined but nefarious cupidity of Verres, and was prized by the polished taste of the

Augustan age. Disdaining the narrow theatre of their native isle, the brothers proceeded into different countries of Greece, which they filled with admiration of their labours. At Smyrna, Bupalus erected his celebrated statue of Fortune, the first, according to Pausanias, dedicated to that deity, and of which a resemblance, with an inscription, undoubtedly spurious, was discovered near Bologna, in the 16th century. Two other inscriptions, both ancient, bearing the name of Bupalus, have been dug up in modern times; one of these on a plinth, found near the crouching Venus, has caused that delicious figure to be ascribed to this artist although evidently of a much later and more refined age. At Smyrna were likewise his Graces in marble gilt, showing how early this practice was introduced; and Pliny mentions with great praise a Diana as appearing stern to approaching, but gracious to retiring votaries. It is the besetting sin of Pliny as a critic in the fine arts to attribute complicated expression to sculpture. It seems not to have occurred to him that simplicity in this respect is not only the highest beauty abstractly considered, but is, in this art, from the nature of the imitation, a constituent and necessary quality. Some modern authors, among whom is Falconet, himself a sculptor, have laboured very uselessly endeavouring to prove how this effect might be produced. If it could be attained, the composition would be so much the more defective.

Among other labours, these artists modelled a portrait of the poet Hipponax, who is reported to have been extremely ugly, and who, in revenge, wrote a satire against them, so very severe, that in despair they laid violent hands on themselves. This last circumstance we know from Horace, and from the posterior dates of their works, to be false. The statue of the satirist, however, from the frightful appearance of the visage, is said to have suggested the original idea of the masks worn by comic actors; for before they were accustomed to appear upon the stage having their features ludicrously smeared with vermilion.

At Delos, where they appear to have long remained, the brothers executed many works universally admired; and on which they inscribed the following verse: "The sons of Anthermus will render thee, O Chios, more renowned than even thy vines have yet done:"—A sentiment in the highest degree pleasing, because, while it expresses the candour of true genius, which dares to estimate its own powers, as well as to do justice to the merits of others, it regards personal distinction only as consecrated by union with patriotism and filial veneration. Happy Greece, who could thus discover incentives to generous exertion in the finest impulses of human feeling! Need we seek remoter causes of the moral grandeur, the intellectual vigour, the refined perceptions of thy favoured sons!

Subsequent to the fiftieth olympiad, all the principles of the arts of design were thus known and exhibited throughout Greece. The rules of painting were well understood, as may be gathered from the descriptions of works executed prior to this date, and preserved even to the age of the emperors. Portrait painting was much practised, and could boast of able masters, as witness the portrait of Sappho by Leon, painted about the forty-fifth olympiad, and preserving its freshness to the time of Trajan. From this may be deduced, not only the exercise of the art, but likewise that its professors had skill sufficient to render their works even more durable than can be effected by any method known at present. Much has been conjectured respecting the painting of the ancients. One thing is certain, that wax was employed to impart adhesion in all instances, and latterly consistency to the colours. To us it therefore appears not improbable, that there were two distinct operations practised in different ages of the art. By the early artists prior to, and about the time of which we now speak, the colours appear to have been used in a dry state, similar to crayons; after the piece was thus finished, a transparent preparation of wax was spread over the whole, so as to secure and preserve the tints. This supposition acquires strength from the fact, that such preparations or washes were employed by the statuaries both in wood and marble. These varnishes were of a rose hue, and so hard, that upon the colossal statues of Hercules and Apollo in wood made by Laphaes, a contemporary of Alcæus, this covering remained uninjured in the time of the Antonines. Afterwards *encaustic*, properly so called, in which the wax was incorporated with the colours, was invented. This discovery, however, must have been made at the latest towards the sixtieth olympiad, since it is mentioned by Anacreon. The minuteness of that poet's directions would lead us to suspect that he wished to point out in preference the latter method, which, from its novelty and freshness, would add new beauty to the features of his mistress. About the same time, architecture, as we shall have occasion to show, was understood not only in its indispensable principles of equilibrium, proportion, and durability, but also, contrary to Vitruvius, in those of refined decoration. Sculpture in all its departments, and in all its material principles of imitation, was complete. Engraving on gems had been practised by means of the wheel, from the time of Talus, the relation of Dædalus. Theodorus of Samos had invented the lathe, which was subsequently employed with great dexterity in forming statues of ivory. The superiority of marble was admitted, and the modes of operating with mechanical beauty perfectly known. The art of casting, introduced by the Samian school, had progressively and prodigiously improved; and at this period exhibited some very refined operations in the union of different metals, as witness the works of Alcon, of Aristonides, of Tisagoras, in iron and copper melted together, metals not easily uniting, and difficult of fusion.

Retracing our path over the ages of these discoveries, how are we struck by the slow and painful growth of human inventions! Fixing undistracted attention upon the life of any one artist now mentioned, how crowded with anxieties and active industry must that span have been! To the individual how momentous those cares; yet how feeble their results compared with the final sum of knowledge, which, they were valuable only as they contributed to swell,—a lesson of humility to the greatest; yet, again, how precious as a portion of the general experience,—a subject of gratulation to the weakest. How small the drop of liquid nectar with which each labourer hastens to the hive, yet of such is accumulated the whole treasury of sweets. The collective energies and discoveries of a thousand years were required to rear the arts of Greece, not to their perfection, but to the state whence the first approaches towards excellence begin to be apparent. From the era of Dipænus and Scyllis, in the 4134th of the Julian period, to the 3090th of the same, being the age of those ancient artists whose sculptures certainly exhibited a rude resemblance to the human form long prior to the performances of Dædalus, there occurs an interval of 1044 years. During the course of this time, as remarked by Varro with characteristic simplicity, but with that veracity and good sense which distinguish his unpretending narrative, the arts were invented in Greece.

The first decided improvement fixed on such principles as enabled succeeding efforts to carry it forward, certainly commences, as already stated, with Dipænus and Scyllis in the 50th olympiad. The advancement regarded chiefly a more masterly execution. This was perhaps in part owing to introducing the stronger marking, necessary to effect in metal, into their marble statues. This manner, although productive of harshness, paved the way for a firmness and decision of handling, which subsequently broke in upon the timidity and feebleness of the ancient style. Melioration to a very great extent, not only in the execution, but in the general composition and perceptions of beauty, were to be observed in the works of Bupalus and Anthermus. On this account, we have been more copious in the account of these artists. Between the Cretan and the Chian brothers, however, that is from the 50th to the 60th olympiad, many contemporaries were actively engaged in promoting the art. Nor was the course of improvement limited to the islands or cities of Greece; in Italy and Sicily, excellent artists were to be found, who carried into those distant settlements the science they had acquired in the schools of the mother country. At Rhegium, Clearchus was celebrated both as an artist and an instructor. At Agrigentum, Perillus cast the famous bull of Phalaris, afterwards carried off by the Carthaginians, and restored by Scipio. It must furnish a proof of our not having overrated the science of this age, that the identical work in question is much praised by Cicero.

During the period, also, of which we now write, and prior to the 60th olympiad, Pisistratus had already laid the foundation of the future grandeur of Athens as a school of sculpture. The wisdom, moderation, and intelligence of this wonderful man, evince how unmeaning were the ideas attached by the Greeks to the word tyrant in particular, and furnish a proof in general of the extent to which they were the dupes of names, and of misjudging prejudice. Happy for Athens had she always been governed by such men; by those who, like Pisistratus, would have respected the essentials of free institutions,—that is, who would have consecrated the resources of the country to promote the national grandeur, and saved her from the worst enemy, her own mob, miscalled freemen. Our own days are not without their cant and catch-the-vulgar terms, against which governors like Pisistratus are our only safeguard. Round him he collected in Athens the most esteemed artists of the time, among whom Eucharis, the son of Athenian Eubulides, a sculptor of the last age, and Callon of Elis were conspicuous. By these two was worked the famous statue of Bacchus, in which were preserved the lineaments of their patron, who was at once the most accomplished and the handsomest man of his age. Eucharis rendered himself famous by his statues of athletæ and warriors in armour. Callon's greatest work was in bronze; the statues of thirty-five youths of Messina, who, with their preceptor and flute player, perished in crossing to Rhegium, in order to solemnize a religious ceremony.

Within this period, is to be placed also another artist of deserved celebrity, Callimachus, the inventor of the Corinthian capital. In adopting this chronology, differing so widely from the received opinion which fixes the date of this invention much later, it will be requisite to condescend upon some details. First then, the account of Vitruvius, who has been followed as the authority in this matter, cannot be correct. He states, that Callimachus, the inventor of the Corinthian order, was the same with the sculptor of the statue of Zeno, the Stoic, and consequently who must have lived in the one hundred and twentieth olympiad. But this order was employed by Scopas in a temple erected at the very latest, prior to the one hundred and fourth olympiad, or more than sixty years before the time of Zeno. Such is the negative evidence in support of our position. But, in the second place, there is positive knowledge that an artist of this name did live at the period now treated of. This information is derived from a relievo, not long since examined by us in the museum of the Capitol, on which the name of Callimachus, as the sculptor, is inscribed. This monument, discovered in the ruins of Horta, and representing four figures engaged in the rites of Bacchus, exhibits the style of art which has been described as characterizing the era of the fiftieth olympiad. There is the same dryness and rigidity of execution, the same elaborate minuteness of detail, and the drapery is arranged in the same symmetrical manner in triangles. These, especially the last, we know were not the peculiarities of any succeeding age. This proves, that a sculptor of the name did live between the fiftieth and sixtieth olympiad: but another step is wanting to the desired conclusion. This step is furnished also by a relievo, preserving the advantage of deducing all the proofs from the art itself. In this bas relief, formerly in the villa Albani, but of which we judge only from an engraving, not having been able when at Rome to discover the original, is represented a muse, accompanied by two other figures, who is receiving a cup into which a winged genius pours liquid from a vase. The style of this production is in every respect similar to that in the one just described, evidently proving it to be of the same age, and although not inscribed with his name, most probably also by Callimachus, since the position in one of the figures is almost a rescript from the preceding. What brings this work to bear on the point at issue is, that behind a wall, in front of which the figures are placed, appears a temple in strong and distinct relief, with capitals of the Corinthian order. From the force of this evidence, it is difficult to escape, except by supposing, of which there is no proof or cause to be assigned, that the wall and temple were subsequently added. The subject is certainly involved in doubt, nor do we assert with confidence; yet as the statement of Vitruvius is evidently untenable, it is therefore extremely probable, rating the evidence at the lowest, that our view of the era of this invention is correct. Callimachus is further praised as master of all the arts of design, and as infusing a greater degree of lightness into his composition than had before been attained.

During the period of fifty-eight years, from the sixtieth olympiad at which the narrative has now arrived, to the battle of Marathon and the early contemporaries of Phidias, sculpture was vigorously exercised, and with corresponding improvement. The exercise was owing to those various political or religious causes which rendered the cultivation of this art essential in most of the Grecian states. The melioration, though in a secondary degree depending upon the same causes which cherished the practice of statuary, was chiefly derived from the excellent mode of study, which, with the intuition of genius, the Greeks from the first had discovered and fortunately pursued. Nature is at once the parent, the object, and the perfection of art. Nature, the only source of excellence, furnished to the sculptors of this favoured country their first principles, in opposition to all systems of conventional imitation. The very faults of their early masters, we have seen, sprung from a too great solicitude to render faithfully minute peculiarities, without attending to selection. But about the period which we are now commencing, iconic statues, especially those of the conquerors in their public games, introduced a more generous study of nature, and furnished new rules of art. To the honour of those who had obtained three crowns, statues, in every lineament individual portraits, were erected. This was attended with a twofold advantage. The practice necessarily rendered living artists familiar with the most perfect examples of corporeal beauty; while it bequeathed to succeeding ages a series of the most valuable, because real models. From these transcripts of the most beautiful living forms, were afterwards deduced those laws of proportion and of ordonnance, which contributed so much to the perfection, as they constituted one of the distinguishing merits of Grecian sculpture. The best of these works were certainly not executed till long after the period of which we are now more immediately speaking; but this source of improvement first assumes importance soon after the sixtieth olympiad. The interval, indeed, between this latter date and the battle of Marathon, represents a species of middle age connecting the empyrical skill and casual beauties of earlier times, with the regular knowledge and scientific excellencies of succeeding masters. The art was now in possession of all the means and instruments,—the correct application of which bounds the aspirings and the praise of mediocrity,—but which merely become subservient to the lofty aims of genius. During the above period, these means and instruments were industriously and far from unskilfully employed, yet few names have been preserved. The movement was one of diffuse activity, not an impulse derived from and sustained amongst a few leading minds. To claim remembrance, no prominent events or actors were presented; and the poverty of anecdote seems to have been occasioned not so much by inattention, as from little being worthy of separate notice.

Dameas of Crotona is mentioned with praise as the sculptor of a bronze iconic statue of his celebrated compatriot Milo. Among the wonderful displays of strength attributed to the original, it is recorded that he bore this figure on his shoulders to the site of erection at Elis. From a law then first introduced, permitting a statue of an athleta to be placed in that city, this work must have been executed soon after the sixty-first olympiad. Polycletus, the first of the name, studied under Ageladas of Argos, of which city he himself was a native, and appears to have assisted his master in the statue of Cleosthenes, who gained the Chariot race in the sixty-seventh olympiad, and was therefore represented in a car. This, consequently, was one of the most important works yet ventured upon, on which account it is the more to be regretted that an idle dispute has been raised about the date of the work, originating apparently from Suidas giving Geladas, and one of the scholiasts Eladas, for Ageladas, who has thus been mistaken for the master of Phidias. The works of the first Polycletus exhibited vigorous conception, but by Pausanias are blamed as angular and mannered in design, "being square and all nearly alike." He had for his pupils Canachus and Aristocles, brothers, heads of the school of Sicyon, each of whom executed one of three muses, esteemed the finest performances till then beheld in Greece; the third was by Ageladas, the master of their common instructor. The work of Aristocles is supposed still to be in existence as the celebrated antique of the Barbarini palace which holds the smaller lyre, and is about twice the natural size. Contemporary with the two last was Ascarus, known by his Jupiter crowned with flowers at Elis; rather later were Menecmus and Soidas of Naupactus, who conjointly finished a statue of Diana, long afterwards removed by order of Augustus. Menecmus was also the author of a treatise on his art, according to Pliny, who has, however, placed both too far in advance.

About the era of the battle of Marathon, although the work in question was probably executed subsequently to that glorious achievement, lived Egesias, whose statues of the Dioscorides have in modern times acquired him fictitious renown. The original work was by order of Augustus, placed in front of the temple of Jupiter, and by most writers has been described as recovered in the colossal group which, now placed before the pontifical palace, constitutes one of the most valued monuments of Rome. It is wonderful how far love of a favourite opinion will lead even the best informed writers. Winklemann, for instance, pretends to find in "those parts truly ancient," the harshness of style for which Egesias is blamed by Quinctilian. Others again draw their arguments from the situation where these figures were found, as being the station of the work of that artist. Now in answer to all this, the group of Egesias is distinctly asserted by Pliny, who had seen it, to have been of bronze—the figures at Rome are of marble: instead of the ruins in the forum—these latter were discovered in the quarter of the Jews. This inquiry here is of importance. These antiques are by the best judges considered to be of the era, if not from the hand of Phidias, and therefore furnish most valuable evidence whence to determine the highest principles of art among the Greeks. This subject, also, has something of peculiar interest to us, since from one of these antiques, with what credit to the national taste others may decide, is copied the national monument erected in the capital, to perpetuate the last glorious but tremendous effort of our arms at Waterloo.

The victory of Marathon, gained in the third year of the seventy-fourth olympiad, or A. C. 490, inspired fresh vigour into the genius and institutions of Greece. From this event is to be dated the commencement of an era, perhaps even more important in her moral and intellectual than in her political history. Preparations had long been making; materials on no small scale were collected in almost every field of mental enterprise: and the fervent spirit of the nation required only an external impulse fully to awaken into mighty splendour its slumbering fires. Poetry had already attained excellence in two of its noblest branches—the epic and lyric: and one year after the battle, Æschylus obtained the first wreath placed on the awful brow of tragedy. Composition in prose had long been practised with a degree of accuracy, and the artists recently mentioned, while early contemporaries of Pherycides were in their last years witnesses to the triumph of Herodotus. Philosophy and science had begun to lead men to relish the charms of wisdom, and to appreciate the powers of knowledge. Eloquence, long admired as the natural endowment of energetic minds, had made some progress as an acquisition subject to precept. In the arts of design we have already shown the preparations to have been even more ample. The fruits of these, indeed, remained in the latter at an immeasurable distance; for in poetry, Homer, Pindar, Sappho, Anacreon —had respectively attained perfection in their spheres. The fame of the sculptor, however, or of the painter, rests upon far less independent exertions of the mind than that of the poet. Their success is determined more by the circumstances of the times, and by national prosperity. Hence the defeat of the barbarians and the resulting consciousness of power—the true foundation of greatness, with capture of their wealth, which supplied means, must have proved even more advantageous to sculpture.

From these analogies we might venture to infer the relative excellence attained in the several provinces of taste. The series of works in art is limited and very imperfect, especially of the early ages; but there have been preserved progressive examples of poetical composition. The genius of Æschylus was formed prior to the first invasion of the barbarians, he bore arms in the fields both of Marathon and Platea. The youthful Sophocles, whose tender age was fitted only for such gentle service, performed in the chorus which celebrated the latter victory. Not twenty years had elapsed when the tragic crown was removed from the head of the warrior bard, and placed on the brow of his rival. During the same spirit-stirring period, sculpture was studied with at least equal zeal,—may it not be assumed with similar success? And that the superiority of the Œdipus of Sophocles, over the Promotheus of Æschylus was not greater than were the majesty and beauty of the Jupiter or Minerva of Phidias compared with the Jupiter of Eladas, or the Diana of Soidas. The improvement indeed would not be so conspicuous in the latter as in the former case: for in sculpture, external art, which to the majority is all, had already nearly approached its utmost beauty; there remained to be added only those intellectual refinements, the triumphs of genius, which, though immeasurably beyond the highest efforts of mechanical representation, are yet less generally perceived. This comparison of art with art in opposite provinces, furnishes a means of ascertaining not only the relative progress, but also the ultimate extent of excellence.

Of those artists who were the immediate predecessors or early contemporaries of Phidias, who fill up the interval, perhaps in moral grandeur the brightest in the history of Greece, from the battle of Marathon to the government of Pericles, a few of the principal may now be mentioned. This series we shall conclude with Myron, in whose works the technicalities of formal art were complete, and whose labours close with propriety the first period.

Pythagoras of Rhegium surpassed all his predecessors with whom the previous pages have been occupied. One of the most celebrated works of the kind was by him, the iconic statue of Euthymus, the pugilist, on which Pausanias has bestowed extraordinary commendation. Hardly less celebrated was the statue of Astylus, conqueror in the foot race in the seventy-third and two succeeding olympiads. A performance of a different kind, preserved at Syracuse, representing a Philoctetes, is mentioned by Pliny in terms of the highest admiration. The sufferings endured, and the cause of these,—a festering wound in the leg, were expressed with terrible fidelity, so that the spectators, while they gazed, believed themselves to be seized with the same pains. The figure, to use the words of old Ennius, preserved by Cicero,

> Ejulatu, questu, gemitu, fremitibus
> Resonando multum, flebiles voces refert

But not from the merit of individual pieces only, is Pythagoras entitled to notice. His name is intimately associated with the general advancement of art, as ranking among the inventors of the beautiful theory of abstract proportion which taught to unite elegance with truth; and by the harmonious relation of parts to express physical intelligence or power. A proof of the use and advantages already pointed out, of iconic statues. He also introduced a bolder and more decided mechanical practice, especially in the manner of rendering the hair, which he expressed at once firmly, yet softly, and arranged with unstudied grace. Hence some writers have proposed his as the era by which to establish the antiquity of certain works, but unfortunately for their own views, through a love of partial system, they have placed this period too far in advance.

While Pythagoras, Onatas of Egina, author of an admirable statue of Gelon of Syracuse; Glaucias of Egina, who modelled the famous Theagines of Thasos four hundred times victorious in the public games; Critias, whose works replaced the original statues in bronze of Harmodias and Aristogiton, carried off by Xerxes, and restored by Alexander,—while these and many others were celebrated for their representations of the human figure, Calamis became still more renowned by his statues of horses. These were likewise iconic statues, a proof how early nature was admitted as the only guide in every branch of sculpture. *Calamis jactet exactis equis.* There is, indeed, some question, whether there were not two artists, bearing the name of Pythagoras, equal in age as in reputation, but of different countries. This seems, however, to have been a mistake arising from Pliny inadvertently writing one city for the other,—Leontiam for Rhegium. Pythagoras was originally a goldsmith: hence we may infer, although it is no where directly asserted, that he wrought exclusively in metal. Vases of his workmanship, of exquisite design and execution, were, in the time of Nero, coveted by the great as articles of the highest luxury. By Quinctilian he is extolled above all his predecessors, and for delicacy of style, placed inferior only to Myron.

The true era of no Greek sculptor is more difficult to ascertain than that of Myron. The difficulty is occasioned both by contradictions among the ancient authorities, and by the imperfect manner in which the subject has been investigated. The principles on which Pliny has fixed his epochs of art, are seldom easy to be discerned. Certainly, they do not rarely appear to be merely arbitrary; nor is the supposition of Heyne unfounded, that the Roman, collecting his materials from general history, and finding the principal artists mentioned on the conclusion of the different wars in Greece, the cessation of hostilities affording a resting place whence the historian could look back on minor occurrences, was led to conceive an imaginary connexion between the enjoyment of peace and advancement in the fine arts. According to this theory, he has divided his subject, and, as in the present case, has frequently sacrificed truth to opinion. But his errors here being set aside, the other ancient authorities are consistent. As to the moderns, there is on this particular point such trifling about names, —such gratuitous assumption,—such slavish adherence to pre-conceived notions, as subvert every precept of manly criticism, or independent judgment.

It is admitted that Myron studied under Ageladas of Argos, in whose school he was the fellow student of Polycletus and Pythagoras already mentioned. Consequently, the question here, as involving much of the preceding arrangement, demands particular attention. It may be proper to explain, that we have fixed the era of a sculptor from the time when he is first mentioned as engaged in a work of public estimation. This method has been constantly followed where practicable; otherwise, the date of his most celebrated performance has been assumed as the era of the author. The only deviation from this plan that has been made, and which will be adhered to, is, where several artists have appeared in the same age, the most eminent has been last mentioned. It must be obvious, that a similar arrangement is the only one calculated to afford just views of a progressive art. Let us observe how these principles apply in the present case. Polycletus has been placed in the 65th olympiad, because then associated in a public work with his master: Pythagoras, a superior contemporary next; and lastly, Myron have been noticed. These, Pliny has also made coeval, but has placed them in the 87th olympiad, and posterior to Phidias. This order has either implicitly, and to appearance, without examination, been followed by modern writers; or seemingly struck with the inconsistency of the narrative, they have pursued a middle course, in adhering to the chronology, while, in the course of improvement, they have described the labours of Myron as paving the way for the excellencies of Phidias. But on examining the subject more in detail, we find that Myron, in the earlier part of his career, must have been contemporary with Anacreon, since there is still extant an epigram by the poet on the far-famed heifer of the sculptor. Now, the life of Anacreon cannot be extended beyond the 76th olympiad, since he was born in the 55th and died at the age of 85. There thus remains an interval of more than forty years between Anacreon and the time in which Myron has hitherto been placed. Therefore, it is barely possibility that the youth of the latter fell in with the last days of the former; but it is altogether incredible, that a youth should have produced a work perfect in its kind, admired in every era of the art, and in praise of which not fewer than thirty-six poetical compositions have reached our times. Erynna, likewise, a poetess, much earlier than the death of Anacreon, has mentioned this sculptor; while Pausanias, Quinctilian, and Cicero, compare him with those artists only who lived prior to the 87th olympiad. Lucian alone, who speaks merely of public estimation, makes any reference to a later period. Myron also inscribed his name, and, in the ancient character, upon his statues, both of which circumstances prove their antiquity, as does also the fact, that many of these were executed in wood. This evidence must be held conclusive against the chronology of Pliny; other opposing arguments, therefore, need not be insisted upon, which might be drawn from his own criticisms, as containing remarks utterly irreconcilable with the condition of sculpture, immediately posterior to the age of Phidias.

Myron, a native of Eleutheræ, exercised his profession chiefly at Athens, of which he was a citizen, finishing his principal works in bronze, and his largest in wood. We have consequently no original work of his hand; but there can be no doubt that the famous Discobolos is preserved to us in more than one excellent copy or repetition in marble. From these, we may deduce a fair estimate of the merits of the inventor. The style of Myron appears to have been distinguished for strength, energy, truth, and science. The last, indeed, like Michael Angelo, he has been blamed as having carried too far, to the sacrifice of simplicity, in studied and difficult attitude. There is every reason to believe, however, that the statue in question, representing a young man about to launch from his hand the ponderous disc, used in the public games, faithfully exhibits the position adopted by the ancients in this exercise. Also no false play of muscle, nor any impropriety against the laws of mechanical action, is to be detected; every limb has that movement, calculated to impress and to second a forward and elevated impetus. The objection then has probably originated in the misconception of a passage in Quinctilian, where, speaking of this figure, he employs the words, "Distortum et elaboratum," yet with the obvious intention of commending the novelty and propriety of the composition, in boldly deviating according to the nature of the subject, into untried modes of art.

Iconic statues were by this artist carried to the highest degree of perfection; in which department his portrait of Ladus the foot racer was esteemed a masterpiece unsurpassed in every succeeding age. Poised on one foot, the most difficult of all positions, the figure was in the act of springing forward, and in the language of an ancient writer, "breath seemed to agitate his lungs; and the form was gazed upon as if flying from its pedestal to snatch the crown of victory." Besides this, the Athenians much admired the Bacchus and Eretheus sculptured by their order; as also an Apollo, carried off by Antony, and in consequence of a dream, returned by Augustus. Representations of animals by Myron were equally admirable, and appear to have been even more highly valued; his famous heifer has already been noticed. Originally placed at Athens, it was transported to Rome and remained in the Forum till the days of Procopius in the sixth century. Four oxen behind the temple of Apollo Palatinus, are mentioned by Propertius as little, if at all inferior, and a dog licking his wound, preserved in the temple of Juno, was, like one by Lysippus, esteemed so precious that the lives of the keepers were made responsible for the security of the work. Myron carried mere imitative art to its utmost extent; but in the management of the hair, as also in some slighter respects, he is represented as having retained much of the dry manner of former masters. Sculpture, as the representation of external form he perfected, but as an instrument of touching the heart—of elevating the imagination, he was unable to call forth its powers. He represented nature forcibly and with fidelity, but without grandeur or intellectual expression. Approaches to just conception of abstract beauty may be perceived in the principle which he is said first to have taught, that propriety of parts was beauty, or in other words, that a work of art was beautiful as a whole according as the parts in form and proportion were in accordance with their office and destinations. This, in fact, is the essence of corporeal beauty—the highest refinement of material art, and assigns to external form, independent of mind, the noblest character and expression of which it is susceptible. This is the utmost range attained during the first period, and formed an admirable ground-work for the sublimity, which was added in the following era.

Second Period.

The invasion of the Persians, fatal as it had proved to her ancient monuments, became a chief cause of improvement to the living arts of Greece. Her temples being every where thrown down, the statues of her noblest citizens and most distinguished characters carried off or destroyed—every sentiment of religion, of patriotism, and of private zeal was interested in replacing monuments so sacred. From the state of knowledge also, this restoration could be accomplished in a manner the most perfect, from a single statue to the most spacious temple. By the combined efforts of sculpture and architecture, the ruined cities, and Athens in particular, rose, phœnix-like, more resplendent from their ashes. An universal activity in the cause of the arts was thus spread over Greece, which continued with little distinction of school, from the battle of Platea, to the death of Themistocles. This period embraces the latest and best part of the professional life of Pythagoras and Myron already mentioned, with numerous others of inferior note; among these was Eladas, who formed the statue of Jupiter, erected in honour of that victory, and in whose school Phidias had already become distinguished. Of the style of the intervening age, which thus, coinciding with the pupillage and early labours of this great master, connects the first and second periods of our history, the lions, placed by Themistocles upon the Piræus, and now adorning the arsenal of Venice, afford a fine example. In these, the art has acquired all its external force; and in contemplating the vivacity of attitude, the fidelity and grandeur of detail, the observer may be at a loss to conceive how far room was left for future improvement. To us, indeed, it has occurred, on repeatedly examining these sculptures, that they respire an air of ideality and imaginative composition, not to be found in human figures of the same date. This seems to arise from the mixed forms and expression of the heads, which, though not to be found in nature, yet produce a noble and elevated effect by assimilating, in a manner more easily felt than defined, to those of man. This character is to be traced in all antique representations of the same species; and as regards animals, generally, the ancients appear early to have entertained this as a principle of the ideal. These works were among the few ornaments added by Themistocles; his prudence, satisfied with providing for the security and power of the capital, resigned, with ample means, the care of decoration to his successors.

Every favourable circumstance thus conspired to render the age of Pericles distinguished in the history of Sculpture. His own lofty conceptions were in unison with the animated and exalted tone of general feeling in his native city. Athens, despoiled of her ancient monuments, passionately attached to the cultivation of the fine arts, with flourishing resources, and with such a government, almost of necessity became the abode of its splendour, as she had been the earliest nurse of elegance. Above all—then appeared Phidias in maturity of talent; and it has been a question whether the patron or the artist was the more fortunate in their mutual connection. Neither would have acquired equal renown apart from the other. The commanding mind of the statesman perceived and rendered available the political advantages and wealth of his country, while, with rare magnanimity, he consecrated both to the promotion of her truest glory. The sculptor seized the inspiration of art in its most elevated range; he possessed that rarest and highest of all genius which is at once creative and regular—learned and original; having mastered the entire compass of preceding experience and attainment—such a spirit adding its own heaven-derived stores, gives to art its loftiest sublimity.

Hitherto we have collected our intelligence from every corner of Greece; henceforth the attention is fixed chiefly upon Athens and her sculptors. The subject, in thus becoming more concentrated, is rendered also less uncertain; still doubts and difficulties do occur. There is even considerable diversity of opinion regarding the time of the illustrious founder of the new school. Phidias, by Pliny, has been placed in the eighty-third olympiad; an arrangement which, with more than due animadversion has been censured by Heyne and his followers. On his disgrace, the common misfortune of the friends of Pericles overtook the artist also, who became an exile from that ungrateful city, whose proudest monuments, "the wonder of Greece and of the world," he had reared. He died in banishment before the decease of his patron, which happened in the last year of the eighty-seventh olympiad. For the space of fifteen years Phidias had been director of the works at Athens. Prior to this he had executed the statue of Jupiter, which was finished according to the ancient authorities, in the eighty-third olympiad, the era adopted by the Roman historian. But to the composition of this celebrated work ten years were devoted, while the circumstance of being chosen for an undertaking of such value and magnitude, necessarily implies that he had already attained eminence in his art. Indeed there is evidence that he finished, about the seventy-seventh olympiad, the famous Nemesis from the block of Parian marble left by the Persians on the plain of Marathon, and which they had vainly thought to have reared into a trophy over Greece enslaved.

From these facts, it is apparent that the date fixed upon is neither happily selected as respects the individual, nor calculated to display the continuous improvement of taste. At the same time, the principles of judgment are here so obvious, that the correction needs not to be held up as an extraordinary instance of critical acumen; nor can we justly make any other supposition than that Pliny, injudiciously no doubt in this instance, has chosen the conclusion of a celebrated work as the chronological era of the author. On the other hand, the early labours of Phidias, thus properly extended, justify our previous arrangement of the subject, as they are shown to have corresponded in date with the mature productions of Myron and Pythagoras. This circumstance explains the near approaches to the highest style made by these artists, while they were surpassed by their later contemporary. In fact, to the perfect imitation and exquisite finishing of these, Phidias, while he retained all natural beauties, added grandeur of expression, breadth of effect, and nobleness of form.

The works of this "Homer of sculpture" may be divided into three classes,—Toreutic, that is statues of ivory and other materials,—Statues in bronze—Sculptures in marble. Of these, the first class, with what justice will subsequently be inquired, has attracted the largest share of attention. The colossal statue of the olympian Jupiter adored at Elis, has been described by every ancient writer whose subject led him to speak of the arts. Placed in a temple two hundred and thirty feet long by ninety-five in breadth, the figure seemed too gigantic even for these dimensions. From an anecdote preserved by Strabo, we learn that Phidias being interrogated whence he had derived the divine conception of his composition, replied that the original of his Jupiter was to be found in the following verses of Homer.

> Η και κυανεησιν ἐπ' οφρυσι νεῦσε κρονιων·
> Αμβροσιαι δ' αρα χαιται, ἐπερρωσαντο ανακτος,
> Κρατος απ' αθανατοιο· μέγαν δ' ελέλιξεν Ολυμπον.

This is a description of an effect not of an agent; and the alleged saying of the sculptor, so often repeated, if it mean any thing, can merely imply that he conceived in his mind the idea of a being capable of producing the consequences mentioned. Seated on a splendid throne, the god was represented in an attitude of repose, one hand supporting a figure of victory, the other resting upon a burnished sceptre of precious metals. The body naked to the cincture, was composed of ivory, the hair being of gold with an enamelled crown surrounding the awful head; the lower limbs were clothed in a flowing vestment gemmed with golden flowers and other ornaments. Notwithstanding the colossal proportions of a form sixty feet high, every part was finished with the most scrupulous nicety. The throne also which rose above the head of the figure, was most exquisitely sculptured with sacred and historical subjects; while others were painted in their natural colours by Panænus, the brother of Phidias; and the whole further adorned with precious stones, of which, from an expression of Plato, the eyes also appear to have been composed.

Of dimensions scarcely inferior, and of the same, or if possible, even superior workmanship and materials, was the Minerva of the Parthenon, the glory of Athens, as the Jupiter was of Greece. The figure of the goddess stood upright, armed, one hand grasping a spear, the other holding an image of victory; at her feet lay a shield covered with the most beautiful sculpture, representing on the convex the Amazonian war, the Athenian leader being a portrait of Pericles, a cause of the artist's banishment; on the concave were seen the giants warring against heaven. On the golden sandals, with exquisite delicacy, was portrayed the battle of the Centaurs. In the figure itself, the nude was of ivory, the robes and ornaments of gold, exceeding in value L. 9000 Sterling.

Such was the admiration attached to these works, that those were esteemed unfortunate who, once in their lives, had not been able to behold and admire. Yet, examined according to the precepts of pure sculpture, and in obedience to the rules of refined taste, as cultivated by the Greeks themselves, we question much the legitimacy of the effects produced by these statues.

It is not enough that a work of art does produce on the beholders powerful impressions; it is indispensable to the superiority of such a work that these impressions arise from the appropriate means permitted to the artist. The neglect or denial of this first virtue of imitative art, has, more than any other cause, been fruitful in extravagance, and destructive of genuine beauty. Now, in these stupendous compositions of Phidias, exposed as they were to the gloom of the ancient temple, their vast proportions from very magnitude dimly seen, while the varied lustre of the parts added the force of powerful contrast in light shade and colouring, glowing but unearthly, the effect must have been tremendously imposing. For exciting awful and undefined ideas of superhuman existences—for increasing the mysterious terrors of a superstitious devotion, such effects also were adapted; and in so far doubtless as accomplishing the end in view, the works were perfect. But the feeling was meretricious;—it was an influence derived from other sources than the graceful and unmingled sublimity of fine forms and noble expression; it was altogether diverse from the solemn and simple majesty which constitutes the essence of sculptural representation.

Of the future fortunes of the Minerva little else is known beyond the existence of the statue in the reigns of Constantine and Julian; but respecting the Jupiter various subsequent details have been preserved. The materials composing these statues required the external covering to be formed merely of veneers; this, from the small extension and tenuity of the parts, rendered frequent repairs necessary. Accordingly, so early as the commencement of the Peloponnesian war, soon after the death of Phidias, the Jupiter was repaired and cleaned by Damophon, a Messenian artist of considerable reputation, with whose exertions the Eleans were so well satisfied, that they conferred upon him an honourable mark of their esteem. Afterwards a sculptor appears to have been attached to the temple, to whose care the work of repair was entrusted. In the reign of Julius Cæsar, as we are informed by Eusebius, the figure was partially damaged by lightning. In the reign of Caligula, Memmius received orders to transport this most splendid of heathen divinities to Rome, that the head might be replaced by the portrait of this most abandoned of emperors and of men. The design of a removal was declared impracticable by artists; and the superstitious fears of the Roman governor were wrought upon by the contrivances of the priests, who caused a voice, apparently issuing from the statue, to denounce the destruction of the ship on which so sacred a freight should be placed. From Libanius again we learn, that in the time of Julian the apostate, the Greek artists were engaged in imitating, with the utmost scrupulosity, the Jupiter of Phidias in the minute works on gems, which were then the taste. This noble monument was finally transported to Constantinople about the conclusion of the fourth century by Theodosius the Great, who perhaps reconciled his Christian prejudices by reasoning such as the following verse contains,

——— ——— liceat statuas consistere puras
Artificum magnorum opera. Hæ pulcherrimæ nostræ
Ornamenta cluant patriæ, nec decolor usus
In vitium versæ monumenta coinquinet artis.

The works of Phidias, in bronze, were numerous; so that a question has unnecessarily been agitated whether he ever exercised the art, except in ivory and metal. The general testimony of history, corroborating the personal evidence of both Greek and Roman writers, proves the affirmative. In these materials, however, his labours were of more gigantic magnitude; and, in bronze especially, his Minerva Polias even surpassed, in this respect, the figures already described. This statue, erect, armed, and grasping a spear, was of such majestic proportions, that the crest of the helmet, towering above the battlements of the Acropolis, might be discerned by the mariner as he rounded the promontory of Sunium. This graphic expression, for a distance of twenty-five miles, evinces both the surprising grandeur of the object, and the fine taste of the Attic writers, by whom every thing noble in sentiment or action is constantly associated with local and homefelt impressions. The ornaments, most probably the whole of this statue, were painted by Parrhasius,—a proof that not in the decline, as has been asserted, but in the meridian of refinement, painting was united with sculpture. Indeed we have ourselves remarked, in the most ancient ruins of Magna Grecia, that even the severity of Doric architecture, to heighten the effect of particular members, did not disdain to borrow aids also from colour.

Examining the merits of Phidias in marble sculptures, we enjoy an advantage denied to every other ancient artist. Respecting the most esteemed masterpieces of antiquity, there still exist doubts not altogether groundless, how far our judgments are formed upon the real originals. But in the ornaments of the Parthenon are beheld the conceptions of the mind, and even in some measure the labours of the hand of the great Athenian sculptor. In this our own age and country, we may still admire the identical works, which for seven hundred years formed the unrivalled studies of her artists and writers while yet Greece could boast of art or letters. From an examination of the *Elgin marbles*, then, we shall obtain no imperfect idea of that style and of those very models which the Greeks themselves have pronounced to be the proudest achievement of their genius in sculpture.

In these precious remains are presented, for our inspection, both statues and relievos. The former ornamented the two tympana of the Parthenon, which was amphiprostylous, in compliance with the religious institutions of Athens; while it thus corresponded also to the other edifices and natural entrance of the Acropolis. On the eastern pediment was represented the birth of Minerva; on the western her contest with Neptune. Of these two compositions we possess in all, besides fragments, fourteen pieces, consisting of seventeen figures, more or less mutilated, five belonging to the western, nine to the eastern front. From the centre group of the former, which has fortunately been preserved, it appears that the whole was of heroic size, or at the least double the proportions of nature. Each figure stood completely detached from the wall, being finished with equal care on all sides. In 1676 these breathing productions, over whose fragments taste now mourns with unavailing regret, were entire. Their destruction commenced in 1687, when, by the blowing up of a Turkish magazine during the siege of Athens by the Venetians, the Parthenon, till then almost uninjured, was reduced to a ruin. Thus one of the noblest bequests of the ancient to the modern world—a sacred legacy which more than twenty centuries had respected, and just in the moment when the gift would have been appreciated, was rudely intercepted by the petty mischief of contemptible and semibarbarous warfare.

Of the relievos there are two classes, originally occupying distinct positions on the edifice, and varied also in their respective modes of execution; yet each bearing the undoubted impress of the same master mind. The temple of the Parthenon was constituted of an exterior peristyle, and of an inner cella. The former composed a double portico on the east and west fronts; but single on the flanks; the latter formed a simple parallelogram, with an entrance in the centre of each end. Two fine situations were thus afforded for sculpture in relief,—the intercolumniations of the outer entablature, and the unbroken frize of the cella. In the Doric order, to which the temple belonged, the metopes of the portico might have been either plain or variously ornamented. In the present instance, the embellishments represented the combats of Theseus against the Centaurs; a subject most interesting to the Athenians, of frequent occurrence in the monuments of Attica, and therefore, excluding the beauty of form in which art had clothed the conception, singularly appropriate in the national temple. These designs, of which fifteen have been preserved, display a very bold relief, approaching to full roundness. The invention, action, and grouping, are truly admirable, pertaining to the very highest style of sculpture: but occasionally the execution is unequal, betraying a timidity and meagreness not easily reconcilable with the lofty character of the composition.

The frize of the cella, a surface of more than eighteen hundred square feet, covered with the most exquisite relief, exhibited probably the grandest creation of art in any age. The same subject was continued throughout the whole; the national procession at the opening of the Panathenean festival. Over the principal entrance on the east the solemn representation commenced; here were delineated the principal actors; and to this point an innumerable multitude appeared advancing in two parallel columns along the flanks of the cella, while, on the western front, as the rear of all, various parties were seen,—some hastening to join the right, others the left of the procession. The most varied and animated design pervaded the whole, delineating the living population of Athens on horseback, in chariots, on foot, young and aged, male and female, mingled with functionaries, victims, and sacred insignia. Over all is diffused a character of elevation and enthusiasm befitting the majesty of a religious rite, and sweetly raising the fidelity of nature to the grandeur of the ideal.

Of the entire composition there still remain about two hundred feet containing specimens from each of the sides and fronts. The relief is flat, evincing, in this respect, the nice discrimination of the artist; since, as the work could be viewed from a short distance, and only by the secondary light transmitted through the intercolumniations of the peristyle, strong shadows and high projections would have rendered the effect harsh, and obscured the figures.

In addition to the materials of judgment furnished by these more directly and certainly the works of Phidias, we have also in the British Museum, from the private munificence of his majesty, the Phigalian marbles. These, amounting to about ninety feet in length, formed part of the frize of the temple of Apollo, present a similar character of design, and in all probability are from the school at least of Phidias; as Ictinus, the architect of the Parthenon, built also the temple at Phigalia.

The remains now described are the memorials of Sculpture in its utmost perfection, and discover, fully developed, every exalted principle whether of theory or of practice. Grandeur is the prevailing character but it is the grandeur of true simplicity and nature, devoid of all parade or ostentation of art. The means are forgotten from their very excellence, and in the full accomplishment of the end. The sublimity resembles that produced by eloquence, where, on some elevating subject, the orator, earnestly and with unaffected sincerity, labours to impress his own convictions upon the hearts and affections of his auditors. The Sculpture of Phidias, indeed, might well be assimilated to the Oratory of Demosthenes, in the truth and reality of its images, and in its power of bearing the whole soul along in one engrossing feeling. But in the artist all is sweet and gracious: we are willing captives to the witchery of art. In the orator a sternness and a severity often induce us to struggle against the potency of his spirit.

In this excellence of uniting the graceful and the pleasing with the energetic and sublime, consists the surpassing merit of Phidias. Exquisitely delicate in the minute, he is bold, vigorous, and flowing in the great. His grandeur combines individual delicacy and scrupulousness of detail, with breadth and greatness of general effect. In these remains, indeed, as in all architectural sculpture especially, effect has been studied as a principal aim. Yet nothing appears done for effect. No effort—no exaggeration; every thing is consistent with itself, with the whole, and with nature. So exquisite is that accordance of design, manner, form, and execution, that not one of these could be changed without injury to truth. This is the very essence of grandeur in art, giving to its productions an ease, a grace, a vitality, resembling more the spontaneous overflowings of inspiration, than the laborious offspring of invention and science.

In these respects the ancient critics seem justly to have appreciated the character of Phidias. Pausanias, in describing the Parthenon, bestows the highest encomiums on the sculptures by the artist of the colossal Minerva, without mentioning the name, which he conceived to be thus sufficiently designated. Demetrius Phalereus, contemporary of Praxiteles, and who had consequently the advantage of comparing most directly the two best ages of the art in Greece, says, that only in the sculptures of Phidias was the magnificent united with the delicate style. Plutarch characterizes his works as inimitable for grace and beauty of form. "Nothing," says Cicero, "is more perfect than the statues of Phidias; they enchant the spectator at the first view." Many other testimonies might be added, assigning to his style, and to it alone, majesty, truth, and grace. By modern writers, however, previous to the removal of the remains now described, the merits of Phidias were estimated with scanty justice. The grandeur of his genius had always been admitted, but not unfrequently his works were characterized as retaining a portion of the rudeness and constraint of former ages—as sacrificing beauty to strength and greatness of effect. In giving origin to this censure, Winklemann seems to have consulted neither ancient writers, the works of the artist, nor the abstract principles of just criticism. A glance to either of the two former will afford sufficient proof that no other man has united in his works more of the highest excellences of art. It is in fact this union which truly constitutes beauty, especially in Sculpture, whose sources of pleasing and of moving being few, and derived from the essential elements of form and expression, admit of separation with peculiar disadvantage. But in each of the fine arts, nay even in nature, although beauty may exist in an object incapable, from circumstances, of greatness,—yet the truly grand can never be disjoined from the beautiful, and that in the highest sense of the term. In the case to be considered, more seductive expression, greater delicacy of air, may have been given to the female statues of the succeeding school under Praxiteles; but for that perfect beauty which arises from including the essentials of excellence in the most liberal proportion, dignity, grace, richness, truth, we search successfully in the labours of Phidias alone.

The attentive study of the works of this artist, supplies the criterion by which to judge of the sublime and beautiful in Sculpture. The ideal of Phidias is perfect universal nature—nature freed from individuality and accident. This, the real object of art, he views through no medium of fancy, he imitates according to no conventional principles. He only looks abroad on all existence, refining partial conceptions and partial modes, by the unerring harmony of the whole. The true ideal—the ideal of Phidias—is but the embodied union of whatever of beauty or perfection still lingers among the forms of nature, viewed in her fairest models. Much, indeed, has been conjectured on the import of certain passages in the classic writers, speaking of the divine archetypes of this sculptor; as if he had drawn his materials from an abstract idea existing in his own mind independent of reality. The sublimity and truth of such remarks have been praised. We hesitate not to condemn the sentiment as inconsistent with both, and subversive of the genuine excellence of art. In this also we are borne out by the works now considered. In the Elgin marbles, every conception breathes of humane life and action. So intimately does the representation partake of reality, that in the opinion of the venerable President West, "When we view the young equestrian Athenians, the conviction is forced upon us, that they and their horses actually existed such as we see them." From this opinion, no one who has carefully examined these remains will be inclined to dissent. This happy effect of truth, however, does not arise from an imitation of common nature, for every figure respires of an heroic and elevated character. The science with which the forms are composed, the freedom of their movements, the ease of their attitudes, express the same capability of moving in momentary action as possessed by the living models. This is wholly opposed to any thing strained or remote from every day perceptions, and throws over the whole an air of simple reality. But with these essential qualities of merely imitative art, are united perfect symmetry, the most harmonious contours, the grandest composition, the most refined grace and delicacy. Truth is thus the primary constituent in the ideal of Grecian sculpture. Beauty is the perfect expression of this truth agreeably to the most unblemished forms which general nature presents. In this union of collective excellence and individual verisimilitude, the mind feels and at once acknowledges the presence of the sublime in art. The works of Phidias enable us to unfold these principles in their purest elements, and to trace the modes in which this union is accomplished. It has been the constant aim of this master to ground ideal upon imitative art; to address the imagination by grandeur of composition and perfection of form, while he appealed to the judgment by fidelity of detail and correctness of science. The relations under which truth and imagination produce results at once grand and interesting, have been closely sudied and successfully exhibited. To attain this, after composing his work in the loftiest intelligence of the ideal, this consummate artist has carefully impressed from individual nature, simply and without exaggeration, those fugitive traits of the surface,—as its fleshy texture, the foldings of the skin, the swelling of the muscles, the lubricity of the joints,—which infuse softness and animation, and which all can estimate.

In all that merely meets the eye, the Elgin marbles display the finest keeping with the general nobleness of their character. The execution is perfect, simply because the whole composition is so. The finishing is delicate and even minute, because the extreme beauty of the design required to be rendered with a corresponding care and dexterity. The chiseling is facile, vigorous, and flowing, harmonizing with attitudes and expressions full of grace, dignity, and truth. The touch is broad, the shadows deep and firm, corresponding with, while they increase the grandeur of effect. The style of design is in the strictest acceptation learned; the muscles and marking of the bones are pronounced with a decision and truth we had almost said, unparalleled in any other ancient specimen. In fact the anatomical science of those fragments surpasses in correctness the most perfect of the statues hitherto discovered. As an expression of action, they are in this respect superior to the Apollo; nor can it be doubted, though from mutilation we cannot exactly ascertain, that, as expressive of character, they were at least equal. Yet these, the highest excellences of manual and material art, appear as if they had been altogether unsought; the marble might be supposed spontaneously to have moulded itself after the most exquisite fashion in the very act of obeying the creative impulse of the artist's mind. So total is the absence of all pretension, that this mastery of touch, this matchless exhibition of skill, is at first unseen and unfelt amid the intelligence it conveys, and at last is noticed only as an harmonious element of a perfect whole. When pretension appears in the means it is doubly offensive; here, at the same time, the utmost beauty constantly marks the productions of lofty genius. Homer and Shakspeare in the mere fabric of their poetry are unrivalled. What more harmonious than their verse; what more felicitous than their language! Yet these never obtrude; study, effort, apparent solicitude, is unknown, unsuspected. The numbers flow, the expressions live as the thoughts arose or the feelings kindled in the breast of the bard. The exquisite mechanism operates unobserved. As surrounding imagery is reflected in truest loveliness by the purest and stillest waters, while the medium itself is lost amid the groves and skies which it shadows forth: So art, the mimic of nature, charms the most where this very mimicry is most concealed. In this happy and unobtrusive union of nature and imagination, in remounting without ostentation or convention to the eternal sources of natural beauty and true science, Phidias displays the perfectly sublime of art, and stands unrivalled among the masters of the ancient world.

We have thus reached an era beyond whose general excellence the genius of Greece never attained in Sculpture. But this eminence, though principally reached in the age and by the labours of one man, did not fall with its author. The spirit of Phidias continued to animate the disciples whom he had instructed. Indeed the artists whose names adorn the succeeding portion of this period, may be classed into two schools, receiving their distinctive character according as they closely imitated or more distantly followed their illustrious predecessor. In both, the principles were the same; these could not vary: but their application was made to subjects requiring a modified exhibition of certain distinguishing qualities. The grand has been explained as the characteristic of the style of Phidias. Succeeding masters, despairing to rival in this department, turned to subjects of a softer nature, gradually creating a school whose leading object was the beautiful.

Agoracritus of Paros, and Alcamenes the Athenian, especially the former, were the favourite pupils of Phidias, and approached nearest to the excellence of their master. It is not, however, easy to determine the real merits of these disciples, since their works were directed, if not retouched, by their instructor, and their performances after his death are said to have been inferior. The grand reliefs of the temple of Olympus by Agoracritus, partook of the heroic character of the Phidian school; but the most celebrated statues of Alcamenes, the Venus of the gardens, and the Cupid of Thespis, prove the commencing partiality for less heroic subjects. In a contest for supremacy, each of these artists submitted a statue of Venus to the judgment of the Athenians, who it is said, partially awarded the prize to their fellow citizen. The rejected labour of Agoracritus, subsequently changed into an image of Nemesis, drew more admirers at Ramnus, than its successful rival at Athens. The statue in part is reported to have been by Phidias himself, and its conversion into a representation so opposite, furnishes an illustration of the sentiments of the Greeks regarding the ideal in expression.

At the same period lived Polycletus, the second and most famous of the three who bore that name. Respecting these artists, Pliny and those who follow him, have fallen into great error, admitting only the earliest, and ascribing to him the merits and labours of the three. In this they have completely confounded the chronology, and contradicted the principles of art. The talents of the second Polycletus appear to have been of a high order, and his influence on the future state of sculpture considerable. His greatest work was a colossal statue of Juno, composed of ivory and gold. The figure, in a sitting posture, was erected in the temple of the goddess at Mycenæ, and is described by Strabo. But the genius of Polycletus carried him rather to the imitation of the beautiful than of the grand qualities of his art. Excelling all other artists in the ease and delicacy of his finish, he was deficient in force; and, to use the words of Quinctilian, as he added more than human grace to the figure of man, so he proved unequal to the majesty of the divine form. Dionysius of Halicarnassus, indeed, differs entirely from this criticism, placing this sculptor next in dignity to Phidias. Polycletus himself, however, has decided the controversy by the selection of his subjects from among the young and the fair. His most celebrated works were the statues of two youths, antique copies of which on gems and relievos are still extant. They were both nude, one binding his head with a fillet, hence called Diadumenos; the other holding a spear, hence termed Doryphorus, also said to have been an Iconic statue representing one of the guards of the king of Persia. There is a question whether this or another statue composed the celebrated "canon" from which, as from an unerring rule or measure, all succeeding artists, even Lysippus himself, took their proportions. Pliny makes a distinction, Cicero says the figures were the same. The former writes expressly, the latter incidentally; neither is it likely that an Iconic statue would be selected for the formation of a standard of abstract proportion. A more interesting inquiry is, what really were those "canons" of art among the Greek sculptors, respecting which so much has been conjectured?

Struck with the unerring truth and harmony of the proportions in the works of the Greek sculptors, some have maintained that they possessed a secret knowledge of geometrical rules by which their compositions were in all cases regulated. Certain it is that the ancient masters had compiled treatises on proportion, and that we meet with the expression "mathematical canons of art" on more than one occasion. But when we remark the variety and animation of attitude in the antique statues, it is difficult to reconcile this playful rivalry of life and nature with the undeviating exactitude of geometrical modes. This has led others into the opposite extreme of asserting the whole of antique art to be the empyricism of talent residing untaught in the hand and eye of genius.

Απὸ τῆς κατα την ἑξασιν φαντασιας.

The characteristic of true genius, however, is to be indefatigable in labour, while its privilege is to conceal the effort. The perfection which we admire in the production of Greek statuary sprung from the accumulated experience of centuries; rules of proportion in particular were the recorded and methodised results of actual measurements taken from the purest living forms of every age. The Iconic statues of the victorious athletæ, we have already hinted, introduced this practice; and the extreme vigilance of the hellanodists, or judges, appointed to decide on the fidelity of these works in every member, as compared with the living original, served both to improve her arts, and to direct the physical education of the youth of Greece. But in any state of ingenuity, more especially with the limited resources of early art, such exactness, without measuring the model, was impossible. Founding on the principle that the corporeal beauty of man consists in the suitableness of the different parts for their destination, artists, by these measurements, were guided in the composition of ideal works: nor can there be a doubt, from the expressions of Diodorus, Lucian, and particularly of Hippocrates, not to insist on the representations on more than one antique gem, that the proportions thus obtained were collected, not only in treatises, but ranged in tables and scales for practical use. Polycletus carried this theory to perfection. Not satisfied with writing upon this interesting subject, he wished practically to illustrate its precepts, and composed the statue which has led to this discussion. The nature of this work has been much misapprehended. To us it appears that in this figure Polycletus intended to represent a perfect form, whose physical character should display an equal aptitude for every exercise, where strength and agility—power and grace, should be harmoniously united. Nor does the creation of such a standard seem at all chimerical, from comparing and combining tables of living measurements with constant reference to nature. The difficulty truly would consist not so much in the construction as in the effective application of the abstract rule.

Among the contemporaries of Phidias, a most distinguished place was occupied by Ctesilaus, since he divided with that master and Polycletus the public prize of merit for a statue to be dedicated in the temple of the Ephesian Diana. To modern times his name possesses peculiar interest as the reputed author of the third finest male antique in existence—the dying gladiator—popularly—but erroneously so called.

He leans upon his hand—his manly brow
Consents to death, but conquers agony,
And his droop'd head sinks gradually low—
And through his side the last drops ebbing flow
From the deep gash, fall heavy one by one,

Like the first of a thunder-shower; and now
The arena swims before him—he is gone!

The beauty of position is peculiarly striking as illustrative of profound anatomical knowledge. The figure is neither resting nor falling, but simply seeking to breathe exactly in the only posture in which, from a wound in the thorax, this function can be performed. Into the interminable question of the subject represented we enter not; but from the grand, learned, and feeling style of this astonishing composition, we hesitate not to place it in the best era of sculpture, being in all respects worthy of that artist, *qui nobiles viros nobiliores fecit*, and who succeeded in competition with Phidias. The assignment of the work to this particular artist, indeed, rests upon an erroneous application of a passage in Pliny, where he says that "Ctesilaus made the statue of a man wounded and dying *in quo possit intelligi quantum restet animæ.*" This description was inconsiderately applied to the statue in question. It was easy for subsequent inquirers to observe that the critic spoke of a bronze, not a marble figure. Hence the originality of the latter was denied. Whether the premises or the inference be here the more illogical, or how the merits of a work of art can be implicated in the non-application of a passage in an ancient author with which it has no connection, it is impossible to determine. The truth is, we know not the artist, but we must acknowledge the presence of the highest art. Surely those who speak of a copy have not gone morning after morning to the capitol, and have found in this dying hero proofs constantly renewed of the immortal energies of the human mind.

During thirty years from the death of Phidias, the Peloponnesian war raged without intermission, involving as principals or allies every state in Greece. In the midst of these hostile commotions, the arts flourished with almost unimpaired vigour. There was united with the sentiment of hostility a spirit of rivalry, which rendered the contention a striving for mastery in every excellence. Sculpture, indeed, appears to have participated largely in the fortunes of Athens, and consequently, towards the close of the contest, suffered some depression. Perhaps the same might be true of painting also. The cause of this seems to be found in the circumstance, that during this tempestuous interval no new style was attempted, while the principles of the grand and the beautiful in sculpture had emanated from the Athenian school, and thither the artists of all Greece resorted for instruction. Also the imitative arts, in their essential qualities rarely derive any permanent impress from passing events; on the contrary, literature, which more easily borrows its hues from the complexion of the times, received, during the same period, quite a distinctive character; and Attic eloquence especially, then assumed that conciseness and vigour for which its remains are still so eminently distinguished.

More than fifty names of eminent sculptors, including his contemporaries, have been preserved, who flourished from the time of Phidias to the hundredth olympiad. Of these Naucydes was the author of the youth holding a discus, and considering with himself the distance to which his preceding competitor has just attained: *Spatium jam immane parabat.* Of this figure three antique repetitions still remain, which are admired for their fine pose, the sweetness and variety of contour, and unaffected expression. Patrocles executed in bronze, thirty-one statues of the Spartan generals and allies at the battle of Ægospotamos. Others we need not mention.

The style of Scopas constitutes in some measure an intermediate gradation between the Phidian and the school of Praxiteles. He was of Paros, and though much uncertainty prevails in the dates assumed by different writers, yet since he was one of four artists engaged to adorn the tomb of Mausolus, this fixes the era to the 102d olympiad, or 370 years B. C. Grace, softness, and truth, distinguished the performances of this artist, of which qualities his Venus and Bacchante were the most celebrated examples, dividing with the subsequent works of Praxiteles the admiration of Greece. Of Scopas two famous works are said to be still extant, the Venus in the Townley collection, and the Niobe at Florence. The former is a standing figure, draped from the cincture by a robe which enfolds the lower limbs only; and whether we regard the beauties of the composition, or its fine preservation, is undoubtedly among the most valuable remains of art in the world. Pliny is divided between Scopas and Praxiteles, as to who was the author of the group of Niobe, while the writer in the Anthologia assigns it to the latter.

While mourning o'er my hapless offspring's fate,
Stone I became through the celestial hate;
The doom revers'd Praxiteles has shown
By whom I live again and grieve in stone!

In this group, which originally consisted of sixteen figures, and of whose transportation from Greece we know nothing, the style assimilates closely to that of Phidias; there is the same grandeur of effect, dignity of expression, and delicacy, yet breadth of detail. The forms also like his are robust, without being inelegant, awing rather by the majesty of virtue, than subduing by the mere allurements of loveliness. The expression of fear, grief, and consternation in the countenance of the mother, is exquisitely true to nature, without injury to beauty, and worthy of Scopas, who is termed δημιουργος αληθειας, *artist of truth.*

Scopas had for assistants, or rivals in the erection of the Mausoleum, Leochares Bryaxis and Timotheus. These, with other less celebrated names, fill up the interval to the age of Lysippus and Praxiteles, falling in with a very unsettled period in the political history of Greece. The rise of the Spartan power upon the ruins of that of Athens; the hateful dominion of the thirty; the virtuous struggles of Thrasybulus and Conon, ending in the restoration of liberty with some degree of power; had kept the latter state in continual agitation. Finally, the ambition of Thebes, which, with the solitary exception of Pindar, had added not one gem to the intellectual crown of Greece, rekindled the rage of general hostility. This terminated in the impious battle of Mantinea, where, to gratify the ambition, or hide the disappointment of one man, were assembled for mutual slaughter two of the greatest and most gallant armies Greece had ever seen—men who could have liberated and enlightened the world. Still the arts shed a pure and softening light over the dreariness of the scene; their brightness, like the dewy arch spanning a troubled sky, might be partially broken and obscured; but elsewhere in every calmer spot—in Sicily, in Rhodes, in the Greek cities of Italy, the splendour continued unimpaired, or even derived fresh accessions from the distractions of the native schools.

Lysippus of Sicyon, as is well known, was the contemporary and the favourite artist of Alexander. Coeval with that prince was also Praxiteles; both sculptors belonged to the same age, and the discussions which have been agitated on this subject, seem to have been quite gratuitous. Lysippus wrought exclusively in bronze, but of the six hundred and ten works which he is said to have produced, not one can be proven to remain; the bust at Portici requires to be authenticated; the horses brought from Chios to Constantinople by Theodosius the younger, and since the year 1204, placed in St. Marks at Venice, have, we think, with justice been pronounced unequal to the fame of their alleged author. We learn from ancient writers, that the style of Lysippus was more grave and severe than the genius of contemporary art; and that he seemed desirous of recalling the more solemn grandeur of preceding masters. This predilection would naturally be cherished by his materials and subjects. Colossal and equestrian statues in bronze demanded forceful, vigorous, and dignified composition. His greatest works were the Tarentine Jupiter sixty feet high, of cast metal, and twenty-one equestrian statues of Alexander's body guards who fell at the Granicus defending their prince. To Chares also his favourite pupil, is ascribed by Cicero the famous colossus of Rhodes. But Lysippus proved himself equal to works the most beautiful and delicate; his finishing was exquisite, his imitation of nature most faithful, and he excelled in his knowledge and expression of symmetry. Of all the artists of this age, his education appears to have been the most complete. He commenced his study where art itself had begun—with nature, and finished them by confirming and applying the precepts thus obtained according to the practice of the greatest masters, if, indeed, a greater than himself can be found. The esteem of Alexander is confirmed by the unanimous testimony of all writers, and, by the admiration in which his works were held, long after the approbation of a prince would have been as nothing. A statue by this artist representing a naked youth preparing for exercise, had been carried to Rome in the time of Augustus, being placed in the baths of Agrippa, it formed the delight of all ranks. In the reign of Tiberius it was removed by his order to the imperial palace, but the Romans rose as one man, and, by their remonstrances, caused the work to be restored. *Princepsque*, says Pliny, *quanquam adamatum reposuerit*.

The influence exercised by Praxiteles upon the progress and character of sculpture, seems to have been misunderstood. In almost every age he has received praise from each successive writer, as an original inventor, as the discoverer of a new style. Yet notwithstanding the supreme beauty of his labours, and the superiority of his genius, we deem this estimate irreconcilable with the history or the philosophy of art. With equal propriety might Sappho or Anacreon be styled inventors in lyric poetry, because their sweetness is not the majesty of Pindar. It has been shown that all the sublimities of which imitative or ideal art is capable, were attained in the works of Phidias. From the era of that master, a gradual declension has been traced from the loftier and severer style to one of gentler subject and softer manner. Without decay of talent, various causes might combine to operate this change—fewer opportunities of great undertakings, a gradual revolution in the opinions and usages of society, works of art becoming more the objects of private patronage than of public munificence, and consequently of private taste. Likewise, it must be admitted, that in all the various departments in which the human mind can be exercised, there is not to be found in the annals of any nation a lengthened display of the very highest genius. As respects the intellectual empire even of the species, a few elevated spirits only are placed in the solitary majesty of general eminence. Succeeding aspirants are contented to select some particular province which they may cultivate and render their own. Thus Praxiteles, falling in with the current of general predilection, and following, it may be, the bias of his own mind, resolved to woo exclusively the milder graces of his art. In this pursuit, he proved conspicuously successful. He has caught the happy medium between the stern sublimity which awes, and the beauty which merely seduces—between the external allurements of form and the loftier but colder charms of intellectuality. In his, of all the works of antiquity, we especially admire softness united with force and elasticity—where refinement has not degenerated into affectation, nor the elegant into the artificial. Over his compositions he has diffused a perfect grace—an harmonious movement if the word may be allowed—a voluptuous majesty—an expression spiritual at once and sensual, confessed by the coldest heart, satisfying the most fastidious taste, admired by the most trembling modesty.

The truth of this encomium will be borne out by the fine antique repetitions of the statues of this master. Or if of these the Faun so renowned among the ancients under the name περιβόητος be really the Barbarini Faun, and the Thespian Cupid, the same marble now in the capitol, the originals will not detract from the justness of the criticism; they place their author first among sculptors of the school of beauty. The Faun is an example of manly grace and of the finest science, and shows that Praxiteles had not selected the graceful because he could not have attained the sublime and forceful. The Cupid is instinct with playful and elegant fancy; and by a well-known artifice of Phryne we possess the artist's own opinion of the superlativeness of this and the former, over every other of his works. The Apollo Sauroc-thonos, as the figure about to kill a lizard has been termed, exhibits whatever of simplicity and elegance can be supposed to exist in boyhood. In the nascent forms the artist has expressed with astonishing truth the promise of future nobleness, in this encountering one of the most perilous experiments in his profession, nor in the whole range of ancient art, is it clear that there could be pointed out an example of greater difficulty more exquisitely overcome. To this work Martial alludes in the following epigram.

> Spare foolish youth! the creeping insect there,
> Death from thy hand it courts—than life more fair.

Praxiteles was the first, perhaps the only sculptor who attained to the true ideal—the perfect union of intellectual charm with feminine grace in the representations of the "Queen of soft desire." His draped and nude, or Coan and Gnidian Venus, fixed each a standard from which succeeding invention dared scarcely to depart. In the Medicean, we almost possess the Venus of Gnidos, the admiration of antiquity, and which in this representative "still enchants the world."

> There, too, the goddess loves in stone, and fills
> The air around with beauty; we enhale
> The ambrosial aspect, which beheld instils
> Part of its immortality; the veil
> Of heaven is half withdrawn; within the pale
> We stand, and in that form and face behold
> What mind can make when nature's self would fail.

Third Period.

The circumstances of birth enabling him to profit by the distractions of the times, had elevated the son of Philip to a situation and to an interference in the affairs of the world which not his talents, far less his virtues entitled him to hold. Circumstances again, yet more than his own intrinsic weight in the scale, conspired to render the death of Alexander a memorable epoch in the history of human transactions. Rather through the fears and jealousies of others than elevated by his own conduct, he had become the sole point of union in an artificial and unnatural system, whose gigantic extent necessarily produced on its dissolution a fearful reaction. Greece particularly, in consequence of this shock, was exposed to the rapacity and misrule of successive masters. Despots assumed sway over this fair domain of freedom and of elegance, not one, but multiplied in almost every city.

Literature and the arts, as adding to the splendour of his empire, had been patronised, and merit liberally encouraged by this conqueror. The distant warfare also in which he was engaged, while it drew off her turbulent spirits, poured into her bosom the riches of the east, thus procuring for Greece an interval of prosperity and repose. Never had she before displayed a more imposing assemblage of intellectual worthies. Philosophy and science, sculpture and painting, every department of mind had its representative scarcely inferior to the greatest of her former names. Surely then the death of a despot could not alone have overcast with settled gloom a prospect so glorious? No. Had the free institutions of Greece been then restored; had the moral vigour, the unshaken patriotism of her better days reappeared, even amid wars and revolutions—contests it may be for existence, not empire—her genius and her taste, her arts and letters, would have survived with repaired, perhaps augmented, lustre. Amid such struggles they had been nourished. But the sources of corruption lay deep and incurable in the decay of that moral and political constitution, amid whose sterner and nobler fruits the arts had sprung up an ornamental blossom; and long did they flourish amid the wrecks of liberty—a wreath upon a tomb—a solitary and stunted tree, hiding for a while the unseemly nakedness of the ruin on which it grows.

Sculpture, our more immediate subject, had reached too high a state of excellence—was too generally diffused in its exercise and examples, to suffer immediate or conspicuous deterioration. The numerous disciples of Lysippus and Praxiteles, supported for a length of time the unimpaired science derived from their instructors. Indeed, it has been questioned, and with seeming plausibility, whether a single work now exists more ancient than the age subsequent to the death of Alexander. Pliny and his followers have therefore fallen into great error, in representing this as the date of a most rapid declension, if not extinction, of taste. *Cessavit deinde ars.* In assuming the demise of the Macedonian prince, and the dismemberment of his empire, as the era of decline in the history of Grecian sculpture, we, on the contrary, wish to be understood as pointing to the period in which the causes of that decline were called more directly into active effect. These causes, indeed, had for a length of time been previously preparing; but the conquests—the riches—the patronage—the excitement and spirit of enterprise then operating, retarded their consequences for a season.

The arts of Greece were innate in the constitution of her free states. They depended on—they fell with the vigilance of her magistrates, the incorruptibility of her judges, the bravery of her warriors, and the virtue of her citizens. It is not from this intended to maintain an amiable, although erroneous theory, which history contradicts, namely, that the fine arts have never flourished under despotic governors. The reverse is certainly the case; and in this more than in any other walk of imagination, is the countenance and active assistance of the existing government especially requisite. But we do maintain, that never can these arts flourish where patriotism and popular feelings are not the paramount, or at least the obviously paramount principles of the times. The arts themselves must be essentially free, and they must likewise derive their quickening inspiration from a common sentiment of interest, and free applause of the country. Whatever might be the knowledge or refined taste, however great the power or liberal the patronage of any prince, without awakening a community of feeling in the people, and the honourable zeal inspired by the public service and public estimation, his own solitary influence never could rouse into exertion original or continuous display of national talent. In sculpture and in painting, he might indeed, like Louis XIV. create schools of imitators and of flatterers; but vigorous, true, original genius lives not to be called forth by the smile of a monarch. As well might be expected in the artificial atmosphere of the hot-house, the beauty and the freshness which bloom amid glades and groves, freely visited by the pure breath and blessed light of heaven.

These truths are opposed both to the opinions of those who embrace, and of those who reject the theory. Are they consistent with the history of art? Pisastratus and Pericles, during whose respective administrations sculpture and the arts, in the principal school of Greece, first acquired importance, and attained their highest splendour, were absolute rulers of Athens. But the arts were free. They were applied exclusively to the public service and aggrandizement, while the voice of their fellow-citizens alone decided upon the merit of artists. So powerful was this last influence, that no work could be placed in its destined situation till after a public discussion and full admission of its excellence. Even Phidias prepared for this award with such trembling anxiety, that during the progress of his works, he was accustomed to listen unseen to the animadversions which might be offered. In the Elgin marbles also, parts are finished with a care which, not in the slightest degree contributing to effect in their future position, could have respect only to a close inspection while thus previously exhibited. In the age even of Alexander, the public voice continued to be the sole passport to fame, as it was the sole judge of merit; nor could all the influence of that prince obtain its award for a favourite whom he patronised, and whose failure grieved him more than the loss of a kingdom. Only when the purity of this source of honour was contaminated—only when a writer, fearing an iniquitous decision, could say to his friends, "Why should I go to the scorching valley of Pisa to read before the assembled Greeks; does not your approbation suffice?" Only then did art fall never to rise again? Political causes therefore, as contributing to the advance of sculpture, were essentially popular among the Greeks. And if we consider the epochs among the moderns, in Rome and Florence, it will be found that Julius II. and Leo X. rendered homage to the majesty of genius, and to the power of public sentiment. These pontiffs reared a school of matchless greatness, because they directed the energies of the arts to an undertaking which commanded the deepest sympathies of the whole Catholic world. In Florence, the best age of sculpture did not survive the republic, or at least republican forms; the last favour conferred upon his country by Michael Angelo, was to fortify her capital against the armies of her dukes. Many years afterwards the sculptor was brought back—a corpse to be returned to his native earth. There is in the sympathies which stimulate the exercise of talent, as in those which awaken the social affections—a sweet and gracious influence spreading from breast to breast, and uniting man to his fellow. The moral virtues flourish only in society, and genius lives but in the generous admiration of freemen.

These remarks sufficiently point out the causes of decline in sculpture after the age of Alexander. Into the few remaining details, or the names of artists whose works are now unknown, it seems unnecessary to enter. We may just observe, that not till every institution belonging to the republican times of Greece, and every sanction of a generous nature had been trampled upon, was art extinguished in that country. Not till the Olympic games ceased—till the physical education and martial exercises of the youth were neglected; till the arts, separated from national utility and glory, became the amusement of individuals; till there was no longer public spirit or patriotic feeling—not till all that creates and endears the name of country, had sunk under the military despotism of Rome, did Greece cease to produce artists.

The period of decline has been differently divided into various portions. Each favourable turn of circumstances which enabled the arts to recover a little from their depression, has been exalted into an epoch. But regardless of these transient intervals, we may separate this melancholy subject into two periods of unequal duration, and strongly discriminated in their events. Through both, however, as regards the fortunes of sculpture, we trace a similar declension. Happier views do now and then open upon the art, but the prospect is soon overcast, and the hopes entertained are soon perceived to arise from a brief revival of the practice of art—not a revival of science. A peace, the temporary triumph of some particular state, the influence of princes, might give a short-lived encouragement, and multiply works, imitations of greater names, but could not recal the principles and influences which to the labours of former ages imparted all their grandeur and excellence.

The first of these periods embraces a space of about two hundred years, from the death of Alexander to the final reduction of Greece into a Roman province. The second contains the history of the Roman school of sculpture, which, with various obscurations and revivals, existed to the age of the Antonines, or even of Gallienus. The latter division we have considered as properly belonging to the narrative of the decay of Grecian sculpture, because the Roman school of art was formed solely of plundered specimens, and of transplanted artists from Greece.

Alexander died in the last year of the 114th olympiad, or 324 B. C. At this time, Lysippus was alive, and Praxiteles survived to the 123d olympiad. For nearly forty years then subsequent to the death of the Macedonian prince, there could thus be no decline of genius, but there certainly was a want of encouragement, and a lamentable falling off in national enthusiasm for art. These causes would soon perceptibly operate against the production of great and original undertakings; still the excellence of individual performances would display little, if any, inferiority. If, again, the scholars instructed by these two great men be considered, the period may be greatly extended, during which Greece could have produced sculptors not unworthy of her best days. During this interval must have flourished Cephissodotus, son of Praxiteles, Tauriscus, sculptor of the Toro Farnese, Eubolus, Pamphilus Polyceutus, Agasias, and others. The chronology of Pliny, who assumes the art to have lain dormant in Greece from the 120th to the 150th olympiad, it is impossible to reconcile with these facts. To one of their Macedonian governors, Demetrius Phalereus, under Cassander grandson of Antipater, the Athenians, in the space of one year, erected three hundred and sixty statues of bronze, a proof at once of their means and their skill. Yet so rapidly did their reverse of fortune approach, that a few years afterwards, having engaged in a contest with Thebes against Sparta, they were unable, even by a personal tax upon every description of property, to discharge their quota of the expense. The Achæan league, and the expiring efforts of Greece under the last of her heroes, Aratus and Philopæmon, seem to have infused some degree of vigour into the art. Of these warriors, statues remained to the days of Pausanias; the latter, indeed, is said to have been particularly versed in painting, of which a flourishing school existed in Sicyon, his native country. The unhappy Etolian war proved most destructive to these prospects, and may be considered as giving a fatal blow to the interest of art, since it first taught the Greeks to disregard the sacred rights of the honoured dead, and the privileges of national genius. In this war, temples were first thrown down, statues destroyed, paintings defaced in Greece, and by the hands of Greeks.

The successors of Alexander in Egypt and Asia certainly endeavoured not merely to maintain, but to improve the feeble lights of European civilization spread through these regions by the conquests and policy of their leader. The courts of the Ptolomies and of the Seleucidæ furnished sustenance and protection to the banished sculptors of Greece; but both in Egypt and Syria, letters were cultivated in preference to art. In these foreign seats also, especially at the court of Alexandria, the principles of the great masters appear to have been departed from; and artists, while they multiplied works in a taste between Grecian and barbarous, only hastened the corruption of art. At the court of Pergamos in Asia Minor, a similar preference for science was cherished; but down to the time of Attalus, and the seizure of his kingdom by the Romans, the Pergamenean princes continued the most generous and the most judicious of foreign patrons. Sicily, long one of the favourite abodes of art, even during the early contests of the Romans and Carthaginians, offered an asylum and encouragement to sculptors. Soon, however, from her shores, as also from the Greek cities of Italy, the wide spreading despotism of the republic banished the pursuits of elegance. The capture of Syracuse by Marcellus terminated the glory of Sicily. In these countries, even the Greek language became disused; and as the last badge of servitude, permission was solicited to employ the Latin in their public transactions.

In Greece, the Etolian war was doubly unfortunate, destroying the idea of a common country, and giving cause to the first introduction of the Romans. For once, however, these soldiers were moderate, or they venerated, even in their fallen condition, the mother of arts and arms. Uniting with the victorious Achæans, they defeated the Macedonians, and proclaimed the Grecian cities free. This event occurred in the 145th olympiad, or 194 B. C. and forms the last bright interval in the history of Grecian art,—the setting beam of a long cloudless sun sinking into dreary, everlasting night. For more than thirty years, Greece enjoyed liberty and repose. Sculpture, during this interval, acquired new vigour, and was exercised by many artists of considerable merit, though far inferior to the masters of former times. Of this age, many names have been preserved, the chief of whom were Antheus Callistratus, Polycles, Apollodorus, and Pasiteles. But the liberty of Greece endured only through sufferance. The Romans permitted its enjoyment only because they could take away the blessing at pleasure; or their attention was engaged by more powerful opposition. The same year in which Carthage fell, the Achæan league was dissolved, and Corinth, the capital of the association, levelled with the ground to the sound of Roman trumpets. This ominous peal sounded the death-knell of the liberty and arts of Greece.

Before bidding adieu to this part of the subject, one particular inquiry demands attention; to what age are to be assigned the principal remains of classic sculpture now in existence? This investigation is deserving of far more space than can now be afforded; but a few remarks may not be irrelevant. The different opinions which, in this instance, have been hazarded or maintained, may be referred to one or other of the following:—that these remains are copies executed during the imperial government at Rome from Augustus to Titus inclusive, and some even so low as Hadrian; or secondly, that in the finest pieces we possess the actual originals—productions of the best ages of Greece. The former position is endeavoured to be proved from the fact, that the artists whose names are inscribed upon some of the most celebrated of these master pieces, occur in no writer prior to the era of Pliny; while the works themselves cannot be traced to any ancient description, or where a connection can be ascertained, it is between a bronze original of some older master, and the marble now remaining. To these historical doubts, arguments in favour of the second position are opposed, drawn from the philosophy of art, the style of composition exhibiting too great perfection almost to admit of higher excellence, certainly not showing any of the usual characteristics of works merely copied from others.

Without entering into the merits of this interesting controversy, it may suffice briefly to state our own impressions, derived from a careful examination of the marbles themselves, and comparing the experiences thence obtained, with the analogies supplied by history.

It is difficult, if not impossible to fix beyond even reasonable doubt, the particular era or master of any one of the most esteemed antiques. Two facts, however, may be elicited with a degree of certainty. First, that very few indeed of the ancient statues now existing are originals of celebrated Grecian masters; but secondly, none of the most esteemed of these remains can be ascribed to a period much later than the death of Alexander. From the premises whence these conclusions are derived, all considerations founded on mere omissions in the limited accounts of Pausanias or Pliny are excluded. The positive evidence of these writers, especially of the former, is very valuable; but as he describes such works only as existed in Greece at the period of his travels; and since Pliny's narrative is an abstract, meagre at best, and confessedly inaccurate, arguments drawn from omissions, in such cases can have no weight. It remains then simply to show how copies would be preserved while the originals perished; and that the age we have fixed upon was capable of producing copies so exquisite. The very care with which precious originals were preserved, and the veneration attached to them, became active means, in many respects, the sole means, of their destruction. In fires, in war, during political revolutions, by the fall of edifices, the statues which, being most valuable were placed in the interior, would suffer most. Under the later emperors, when all that was most admired in Grecian statuary was to be found in Rome or Italy, and in Constantinople, religious zeal proved more destructive than either time or warfare. The Iconoclasts would select as objects of peculiar hostility exactly those works over which "the fond idolaters of old" had bent in greatest admiration, and which would now be most highly prized by the cultivated mind. It is easy to perceive how this reasoning applies to the preservation of transcripts from these perished masterpieces. On the death of Alexander, we have seen that the schools of Greece, especially the Athenian, were formed of the disciples of Lysippus and Praxiteles, and that the latter survived that catastrophe many years. For nearly half a century, therefore, there could not be wanting sculptors in Greece equal to the most perfect works now known. But political convulsions rendered this period unfriendly to the advance of art in the production of original performances. Nor is it too much to say, that original genius from this date became more and more rare. At the same time, imitations from the earlier masters were multiplied in every era, as may be proved from the close resemblance existing between innumerable single figures and individual remains which have been copied from the Elgin marbles. The pupils of the two last great sculptors of Greece were employed, then, during this interval, in which the arts, supported solely by individual patronage had first ceased to be the care of the state, in copying, or rather repeating the most admired conceptions of their masters. And to this period we assign the greater part of antique statuary now in the different collections of Europe. Our limits do not admit a more extended detail of proof; but as a general inference, selecting the most beautiful of these works, it may with confidence be affirmed, that whether originals or transcripts, subsequently to the date assumed, they could not have been executed. Considered as a whole, each is so perfect; between the intellectual and material excellence the harmony is so delightful, so complete, as could be obtained. while yet the art languished only in practice from defect of encouragement, but while talent and skill continued unimpaired. It will be found, also, that in works avowedly executed later, although parts separately considered, and portraits especially of the earlier Cæsars, may display the highest beauty; yet this perfection of the whole, this pervading impress of a rich, vigorous, and accurate science—this *imponere totum*, the triumph of art is wanting.

But it may be said, if there be original works of the great masters, how are they to be distinguished, what are the grounds of decision, and why should other productions, hitherto perhaps enjoying equal estimation, be degraded from their rank? These are questions not to be determined without reference to taste merely—a principle always more or less subject to individual modes of thinking and of feeling, or to rules of criticism not fully established, or not universally applicable. Judgment consequently becomes simply an expression of opinion, entitled to deference according to circumstances; beyond this a conclusion ought neither to be urged nor received. The least objectionable criterion of originality seems to be to select a standard, the merits or authenticity of which cannot reasonably be called into dispute. For such a purpose the Elgin marbles appear on the whole most proper. From these, notwithstanding their mutilation, to one versed in similar inquiries, it does not seem impossible to elicit a system of infallible criticism applicable alike to characteristic and to executive art.

Tried by such a standard, while it is compared with itself, and with the history and principles of classic sculpture, a very limited portion indeed of the antique statuary now extant will be found to belong to the age of Phidias, or to be from the hand of an original master. Of the former period, we believe there is but one specimen in Italy, namely, the *Torso* of the *Belvidere*; which compared, for instance, with the Theseus of the Elgin marbles, displays the same bold, learned, and breathing style of composition, and is certainly of the same school, perhaps by the same hand. After this, the Venus de Medici, the Niobe, and the Venus of the capitol, approach nearest to the perfection of the grand and simple style of execution, while the sentiment belongs to the truly beautiful. These are certainly originals of the earlier schools, most probably of Phidias, of Scopas, or of Praxiteles, but not later. With these we rank the Townley Venus or Dione, now in the British Museum. The Apollo we are inclined to consider as a transcript from a bronze original—probably of Lysippus. This opinion is founded not so much on the inaccuracies of detail, as upon the general bearing of the figure, which scarcely seems not adapted to representation in marble so well as in metal, without external support, in addition to the balance obtained from the disposition of the attitude. This is a principle never neglected by the ancient masters. We not unfrequently discover the most exquisite skill employed to unite grace with strength in this respect. On the contrary, copies from bronzes may be often detected by some unbecoming fragment of marble left adhering between the body and an extended member. In some few instances this defect has been obviated by the introduction, or novel distribution of drapery. In the present case, the Chlamys, wrapped round and descending from the right arm, has been added in the Apollo, an arrangement which, though not ungraceful, is inconsistent with the action of the figure. The numerous class of antique sculptures, which may be termed athletic, appear to have been all copied from bronzes, seemingly from the age of Myron down to that of Lysippus. Of these, one of the most celebrated, is with equal impropriety, styled the fighting gladiator or Chabrias. This beautiful form represents a warrior defending himself against an antagonist who stands on vantage ground. Of the Laocoon there is difficulty in speaking with assurance; or rather the praise which has been lavished, both by ancient and modern authors, on this remarkable production, creates a timidity in expressing a dissent from the almost universal applause. Whatever may be the individual excellence of parts, considered as a whole, the work is in more than one respect faulty. The figure of Laocoon himself is truly noble; but those of his sons are in every view unequal accompaniments. They are, in fact, mere mannikins, deficient in expression, in form, and in anatomical science. The position of the principal figure is dignified, natural, and even awfully imposing; their attitude is ill selected and ineffective. While the one is not unworthy of the best ages of Grecian art, the others are by no means superior to works executed under the Antonines in almost its latest decline. The expression, indeed, in the former is more powerful in character, than altogether consistent with that majestic serenity which formed the intellectual ideal of ancient masters. This expression, however, is only a general indication of suffering, and the soul seems struggling to overcome or repress its agony. In the execution there is a meagreness, a dryness, not to be discovered in the age to which the high style of design can properly be referred. We are thus lost in the contradictions which the work presents; and in what era lived Agesander, with his sons Apollodorus and Athenadorus, to whom the work has been assigned, is by no means apparent. Whether, with the Italian and German critics, we place this period between Phidias and Lysippus, or, with the French writers, fix it so low as the first century, during the reign of Titus, the difficulties remain. The figure of Laocoon would do honour even to the former of these ages, but it is impossible for a moment to believe that the children could have been executed in an era of the most perfect art; again, these latter may well belong to an epoch of Roman sculpture, but in the reign of Titus no performance can once be compared with the sublime conception of their aged sire.

We shall not pursue further this examination; the application of the standard proposed, to every remaining specimen of antiquity, may be easily made on the same principles. The conclusions are here ventured as modest expressions of opinion; let it however be remembered that they are formed on no imaginative theory, but on a comparison of art with itself—the only criterion by which the works of art can be classed or estimated. One argument, not yet noticed, may be deduced in opposition, from the names inscribed even upon some of the examples we have selected. This furnishes an opportunity of observing, once for all, that when such inscriptions contradict the chronology implied in the style of the work, the names are certainly not to be considered as those of the original fabricators of the statue. Indeed, in a very few cases only do these names agree with the ordinary tests even of antiquarian criticism. The form of the letters in most, and in some, as the Venus de Medici, grammatical inaccuracy indicate a lower age than could possibly have produced such works. These inscriptions, therefore, are either actual forgeries, a species of literary larceny, or have been affixed on occasion of repairs or restorations by the Greek artists of the empire. Such repairs we know to have been effected, in more than one instance, by command of the reigning emperor.

From the fall of Corinth, Greece is known in the history of the arts only as the unhappy source whence the plundered ornaments of Rome and of the patrician palaces of Italy were torn. Or more unfortunate still, she furnished the talent which, in busts and statues, was to immortalize the lineaments of her enslavers. Or yet greater degradation, she, the nurse of free born genius, was doomed to impart to their manumitted slaves those noble arts which her haughty conquerors disdained to exercise. Cicero has condemned to perpetual infamy the rapacious cruelty of Verres, but in every state of Greece the rapacity, if not the cruelty, was exercised unpunished; even the orator himself did not scruple to beg, as gifts, statues which he could not purchase, and which he knew his more fortunate friends had acquired only by violence. Three thousand statues are reported by ancient writers to have been removed from the isle of Rhodes alone. Corinth was deprived of all; each city yielded up whatever appeared most precious; and this desecration of her temples, this despoiling of her high places, this general sacking of public territories, and revolution of private rights, was not finally completed by the republicans. Greece possessed something of value in sculpture till the close of the first century, during the course of which every portable masterpiece disappeared.

During the latter period of the commonwealth, the practice of the art, but by Greek sculptors, was introduced at Rome. Scylla, Pompey, Cæsar, introduced or first patronised, to an extent equivalent to an introduction, the custom of erecting statues to public men. By thus furnishing employment to the actual arts of Greece, they compensated in some measure the removal of her ancient treasures; but finished by transferring from her soil the remembrance of the dead, and the merits of the living. Of all the nations which have held supremacy on the earth, the Romans show the least claims to originality, or have least impressed the future fate of the human mind by any bold peculiarities, or successful darings of their own genius. The character of their intellectual partakes of the tenor of their warlike achievements. In both this character staid and regular, but neither novel nor much varied; forming part of one system by which care, perseverance, and discipline supply the place, or indeed deny the exercise of the generous but more desultory efforts of native talent or untutored bravery. In warfare they borrowed their principles from enemies by whom they were first beaten, but who in turn were subdued by the addition of Roman vigilance to their own science. They left nothing to chance—no room was given for surprise, and little for stratagem. Each march was marked out—each night the camp fortified—prudence was opposed with success to valour, and they subdued the world by the discipline of the legions, rather than by the heroism of the soldiers. Hence in the history of Roman conquest, we meet with little of that chivalrous enterprise—of bold adventure—and high heroic soldiership which give their spirit-stirring interest to the annals of Grecian or even barbarian warfare. In the regions of imagination and of taste, the progress of their genius resembles the march of their arms on the globe. They have left only modifications of the exquisite materials produced by their predecessors. Yet from the Greeks they have borrowed little which by care and study has not been improved. The improvement, however, extends only to the fabric—not the material, which remains with little alteration and no addition. In fact, had the Romans ceased to exist before the rude ignorance of our forefathers had borrowed from their legislative or rather civil code, not one element of thought—not one discovery which dignifies his nature—not one invention which extends his power, would have been lost to man.

If such be nearly the case in literature, in philosophy, and in every branch depending upon fancy—in the fine arts the originality of Roman genius is still more circumscribed. The character of the national talent seemed indeed well adapted to succeed in sculpture. But three things opposed this: they regarded the art as the peculiar eminence of a conquered people, and its productions as fruits of victory not as triumphs of mind, hence they cherished no genuine enthusiasm, no real respect for its excellencies, they never practised its labours; secondly, their national manners, and the desire they early affected for being represented in armour, were opposed to the advancement of sculpture; and thirdly, the amazing richness and beauty of the Greek specimens so profusely lavished throughout Italy, rendered their masters indifferent to original works, which could not even equal these, and desirous only of portraits. But even the statuary, whether busts or ideal statues, were executed by Greeks, nor does it appear that a single Roman attained eminence in the art. The history of sculpture indeed among this people is distinguished by two singular yet very similar epochs.

In the dawn of her rising fortunes, we have seen that Rome was first adorned by the ravished spoils of

Etruscan art: that sculpture there transplanted, soon decayed or was forgotten, among a warlike and unimaginative people. It would answer little purpose, therefore, to enlarge on the consular and early republican ages: the past borrowed—the living arts are characterized by Tibullus

"Stabat in exigua ligneus æde Deus."

And Cato opposed the introduction of the statuary of Greece, on the plea, that its divine forms would expose to ridicule the rude fashioning of their own deities. As the first era of the art was thus formed by an ineffectual attempt to affiliate the genius of conquered Etruria; so the second exhibits a similar trial, and similar success with subjugated Greece. The history of sculpture in Rome then is but the melancholy continuation of its fate, closing the last faint glories of Grecian art in a strange land.

The reign of Augustus, like that of Alexander, was favourable to the arts only as respected their political influence. The crafty successor of Julius, to conceal the loss of civil liberty, affected to turn the genius of his subjects to intellectual empire. From being the mistress of the world by arms, he aspired to render his capital the seat of elegance and of knowledge. This was but gilding after forging with exquisite nicety the fetters of the once haughty and jealous republicans. The objects here were not those which an innate, a real love of acquirement seeks, yet the external effects in reviving the practice and awarding the professors of the art at least were the same. Rome now became the sole field where the sculptors of Greece, in the exercise of remaining skill, found recompense if not honour. Hence every man of talent began with the first appearance of settled government, to repair thither, and the collecting there all the master pieces of former and better days, added a new inducement. Rome then, as now, came to be regarded by every artist, as

"His country—city of the soul."

Among the sculptors who thus adorned the Augustan age, several names have reached us. Pasiteles, Archesilaus, Zopirus, Evander, Athenians, or Greeks, were the most eminent. The first excelled in metal and as a modeller. His silver statue of Roscius, an infant in the cradle on the point of being strangled by a serpent, an incident in the childhood of the actor, was much admired. The vases of Pasiteles, as also those of Zopirus and Evander, were highly esteemed. The two latter were likewise eminent for relievos in metal.

——— Mensave Catillum
Evandri manibus tritum dejicit.

Archesilaus greatly excelled in works of marble: he is praised by Pliny for his improvements in modelling, and for the care with which he studied his compositions in clay or wax, before attempting to realize his conceptions in more durable materials. Varro describes, with lively simplicity, a group from his hand of one block, the property of Lucullus, representing a lioness with cupids sporting around and forcing her to drink. The Venus Genetrix, ordered by Julius Cæsar of the same artist, so delighted the accomplished patron, that through impatience to dedicate so beautiful a work, he removed it before the last finish had been given;—a defect, however, not to be discovered.

But the movements created by the patronage of Augustus of one who could wield for his purposes the energies of the enlightened world, were too general and too extensive to admit of particular description. Every branch of human pursuit felt more or less the influence. Museums of nature and art crowded the temples; galleries of painting and of statuary assembled whatever was rare, beautiful, or precious in either; libraries were formed, displaying the whole intellectual riches of human science.

"—— Veteres revocavit artes."

As regards our present subject, however, the creative spirit could not be recalled. The remains which undoubtedly belong to this era of sculpture offer the strongest proof how little can be effected by even the most unlimited patronage without the aid of moral causes, in the production of genuine and original talent. To those who extol this reign as capable of such works as the Apollo, we recommend a comparison of that divine figure with any statue of Augustus. Surely an inferior artist would not have been employed upon the likeness of the emperor, while others so much abler could have been procured. Compared with any work having pretensions to Grecian antiquity, these statues are poor in the extreme. Not so the busts of the Roman school, which, without suffering by the contrast, may be confronted with similar works of the best ages of Greece. In this department only do we discover undoubted vestiges of ancient genius; and we believe it will be found, that, forming from these remains their estimate of the state of Roman art generally, writers on the subject have been led into those exaggerated opinions of its excellence already noticed. These busts indeed, from Julius to Gallienus, through a series of three centuries, present some of the most perfect examples of the art in portrait. They do not indeed equal in heroic character one or two remains of Greece, but we are struck with the most powerful representation of individual mental resemblance. Omitting all dry or minute detail in the scrupulous rendering of each separate feature, the artist has addressed himself to the portraiture of the mind. Into the whole movement of the countenance is infused a speaking, a characteristic expression, as if the marble were but the translucent prison of the soul, setting before us the very actor in those deeds which have formed the studies of our youthful years. But this high perfection applies only to the last period of the commonwealth, when each chief of a division among the conscript fathers could have embroiled and would have ruled the world; or extends not beyond the early reign of Augustus, while yet the free and fiery spirits of former times had not learned to quail before a master. As we advance, the impress of grandeur and energy of thought becomes more obscured. The withering influence of despotism, or the debasing contagion of profligacy, spreads a dull and brutal calm over the expression like the mantling of the lake above corruption. The series of the Cæsars, indeed, as furnishing examples of art, continues to be fine, but the expression is too often such as the imagination cares not—or dreads to explore. The fall of material art keeps pace with the decay of internal grandeur. The rapid decline of the only branch of sculpture in which the Roman school attained eminence, is certainly in a great measure to be attributed to the discouragement imposed by the jealous fear of succeeding emperors, who forbade the erection of busts save in their own honour: but there is too much truth in the lament of Pliny, that when there were no longer images of mind, the lineaments of form also degenerated. *Quoniam animorum imagines non sunt, negliguntur etiam corporum.*

From this series of busts, the style of art during the Augustan age, and the different vicissitudes which Roman art has undergone, may be known with great precision. The character of design and of execution is evidently the same as that by which the last era of art in Greece is distinguished. In the finest specimens there is no evidence of new energies added by the union of two separate modifications of talent; nor in the most inferior is there any exhibition of the more original, though perhaps ruder, efforts of an aspiring and distinct national taste. Either or both of these effects must have been perceivable, on the supposition that there were native, previous to the migration of Greek artists. Nothing is more easily discriminated than is the vigorous inaccuracy of rising art from the languid correctness of its decline: and every thing in Roman sculpture discovers a progressive step from a condition of high excellence; every touch shows what has been, not the eminence for which we are to draw upon futurity. When we compare the latest works executed in Greece with the earliest productions of the republican and Augustan ages, there appears in each a continuation of the same principles, with such difference as the political and other causes already noticed, can easily reconcile. The style of design during the period of which we now speak, is accordingly marked by a squareness and decision in the arrangement—a boldness and firmness in the pronouncing of the parts evidently derived from the successors of Lysippus and of Praxiteles. The mastery of touch, indeed, is frequently so bold, as to be redeemed from the imputation of careless and unfinished only by the truth and vigorous meaning of every stroke. Dexterity of mechanical detail is among the last beauties which linger in declining art; it begins first to disappear in those passing lines of thought and form where little meets the outward sight, but in which the science and feeling of the skilful artist are most surely displayed. Striving to recover these, but more by practice of hand than by exercise of mind, the succeeding age still further degrades art by rendering their productions tame, hard, and laboured. The Augustan age of sculpture hovers between these extremes; the masses are large and fine in distant effect, but the details are not clearly made out. The expression of the eyes is studied, and, evidently with the intention of producing an imposing air, the eye-ball is made larger than in nature. The hair is particularly heavy, and, though bold in the general arrangement, is harsh, from a want of a proper and just degree of finish. As compared with the sculpture of the preceding ages, there is, indeed, in the works of this school a general character of harshness. An absence of those sweet and flowing lines, which bring the whole contour fully but graciously upon the sense, yet without palpable obtrusion on the eye; which invest the pure specimens of Greek art with a moving and evanescent shape eluding research, yet circumscribing beauty with the breathing variety of softness and of life.

Such continue to be the leading characteristics of Roman art, under the immediate successors of Augustus. The defects, however, continue to increase, and a considerable degradation is to be perceived even during this reign. A laborious and mannered style, in imitation of the sophists, spread from literature to the arts, and introduced the beginning of the lapse toward the second stage of deterioration, where remaining mechanical skill is wasted on tedious and ineffectual finish—patience of labour supplies the place of vigorous design—and from Augustus to Constantine, the art gradually subsides into worse than pristine feebleness.

The reign of Nero has been considered as peculiarly favourable to sculpture, and has been assumed by Pliny as forming an era in the history of art, which he considers to have been dormant for nearly forty years. That Nero lavished immense sums upon building, painting, and statuary, is true,—he collected from Greece whatever of precious or rare former invaders had spared; but that he improved the actual state, or even retarded the decline of art, may be questioned. His taste like his morals was vitiated, and to him the arts were objects of luxury and vanity, not sources of intellectual pleasure, of which he was incapable. Nor does it argue much for the state of art in Rome, that Zenodorus, a provincial artist of Auvergne, was called from Gaul to cast the famous colossal statue erected in the vestibule of the golden house. The age, however, must have been very far from deficiency of resource or of refinement, in which could be produced a bronze figure one hundred feet high, or the heads of Nero, especially the exquisite likeness as a child, now in the Florentine gallery.

The school which flourished in Rome from the termination of the republic to the reign of Nero, adhered strictly to the principles of the Greek masters, allowing for the defects of general inferiority. The founders or principal artists of this school were Diogenes of Athens, who finished the statues with which Agrippa adorned the Pantheon. Batrachas and Scauros, sculptors and architects, who built and adorned the porticos of Octavia, and whose ingenious hieroglyphic cypher is still to be traced in the frog and the lizard, in the eyes of the volutes, in some ruins of the Forum. This was contrived in order to associate their memory with a building upon which they were prohibited from inscribing their names—the literal meaning of these names being the animals thus artfully introduced. Pliny enumerates and praises many others. Philiscus, Pythodorus, Hermolaus, Artimon, Lysias, &c. whose exact age or labours are not ascertained, but whose names and pupils bring down the art from the republic, through the first eighty years of the Christian era.

The reigns of Vespasian, Titus, and Trajan, were on the whole favourable to Sculpture. The great works of this period, however, being architectural—temples, palaces, and triumphal arches, the sculpture chiefly encouraged was that adapted to the decoration of such erections. This was not calculated to retrieve the lapse of the art, but rather to nourish the deterioration arising from bold and facile execution being preferred to simple and accurate design and natural expression. The bas relief still existing upon the frize of the temple of Minerva, in the Forum of Domitian, instances the truth of this remark. As Winklemann has observed, this figure, for their remains only one, has the appearance of having been merely blocked out, so bold and unfinished is the workmanship,—to the justness of which criticism we can bear witness from having frequently drawn and studied this interesting ruin. The few remaining sculptures on the ruined arch of Titus exhibit the same character, but the monument itself is of fine proportion and design. Architecture, indeed, longer preserved its purity among the Romans than sculpture; such at least appears from the more enduring edifices whose gigantic remains have reached our days. But there is abundant proof from more fragile sources, that even early in the reign of Augustus corruption had commenced in this noble art. The great error in the views introduced by the Roman architects, was a constant aim to lessen the diameter, while they added to the height of their columns. The principle indeed may be generally applied to all supporting members. The solemn grandeur and majestic serenity of the Grecian proportions were thus lost without any increase of lighter grace. The cultivation of such a taste among the Romans becomes the more singular, when considered in connection with the facts, that they were a less imaginative people, less gay in their dispositions than the Greeks, while on the whole, in their grander erections they employed materials of superior mass. In architecture, however, in which no standard of immediate imitation is fixed from natural prototypes, deviation from abstract symmetry once admitted, license has no acknowledged bounds. There exists a tendency in false taste to substitute in this art ingenious contrivance for elegant skill; hence the principle of deterioration above noticed. The enormous pillars of the Egyptians were by the Greeks refined into proportion uniting security with grace. The Romans, aiming at greater lightness, then at surprising, first reduced this proportion, and finally deviated into almost every barbarity of column, paving the way for the fantastic tricks of the Gothic architect, who seems to have placed perfection in setting at apparent defiance the ordinary laws of gravitation.

In the empire, as respects architecture, there also existed a peculiar source of corruption not known to Greece. In the latter, one patron, namely the state, the representative of the public, left the artist untrammelled by the influence of private judgment or individual taste, and free to pursue the general principles of art. In the former, the emperors were not only the sole dispensers of reward, the approvers of merit in works undertaken by their especial order; but the example of their sovereign being followed by wealthy subjects and public functionaries, who, erecting at their own expense, porticos, temples, theatres, aqueducts for the public benefit, claimed and exercised similar rights of private patronage. The art was thus no longer the free servant of the public, but subject to individual taste, against whose exclusive approbation or censure there was found no protection in the common sentiment.

That some of these causes of decline in architecture had begun to operate so early as the reign of Augustus, is obvious from remains, and from pictures recovered from Herculaneum and Pompeii, as also from history. At the period now mentioned, Plutarch informs us, that under Domitian columns of Pentelic marble had been rough hewn at Athens for the temple of Jupiter at Rome, but when finished in their site according to the Roman taste, they had lost their noble proportions, and to an eye practised in the arts of antiquity, seemed about to be crushed by the building which they supported. This taste appears more incongruous still when viewed in comparison with the contemporary style of sculpture as observable in the fragments of the colossal statue of the same Domitian now in the capitol. These immense masses, bold and harsh, but vigorous in their execution, would indicate a state of art the very reverse of what has now been described, and evince the absence of all uniform or consistent principle.

But although corruption was thus at work, the external condition of art was flourishing. Vespasian and Titus erected noble edifices, containing not only the most precious productions of the chisel and the pencil, from the hands of ancient masters, but also adorned with the works of living artists. Of these, such names as Cornelius Pinus, Accius Priscus, would seem to furnish evidence that, in painting at least, natives now began to rival their Grecian instructors. Artists, indeed, educated in Italy were usually freed men: hence our term liberal arts, and in these or other instances, might, therefore, have adopted the names of their former masters—an usage not uncommon. Certain it is, that the whole fabric of Roman art, in its principles and practice, still continued Grecian; while in the succeeding reign of Trajan, an era peculiarly favourable to the arts of the empire, his favourite architect Apollodorus, as well as the sculptors whose names are known, were Greeks.

The arts under this emperor partook of the elements of his personal character. Their applications were grand, substantial, and useful—beautiful in execution; but this beauty subservient to utility. Of the grandeur and enduring character of the erections with which he adorned almost every province of the empire, the triumphal arch at Ancona is an instance composed of the largest masses of any classic work in Europe. But even here, in the proportions of the columns and ornaments, we detect the faulty principle already noticed. Of utility in these works, the harbour of Ancona—of greatness united with beauty, the historical column remains an example. Considered as a monument of labour or of skill, this storied pillar is one of the most wonderful vestiges of the ancient world. Rising amid the spires and domes of the modern city, it is conspicuous by a certain venerable simplicity; and though, with a diameter of eleven feet, attaining an elevation of nearly one hundred and twenty, the whole is composed of only twenty-two blocks of white marble. From the base to the abacus, the exterior surface is covered with sculpture in relief, representing the leading events of the Dacian war; internally is a winding stair hewn from the solid blocks, each of which forms a complete frustum of the pillar. It is this latter adornment which requires our present notice, for in architecture the work constitutes an innovation. These sculptures are contained within a kind of fillet about four feet broad, making in the height of the shaft twenty-three spiral convolutions. The number of figures, including elephants, horses, and warlike engines, amounts to some thousands, all wonderfully varied, and forming subjects of study not less interesting to the artist than to the antiquary. The design and execution are correct and vigorous; the relief well adapted to effect, yet without injury to the general outline. The character and style are decidedly Grecian, though the details are defective or usually wanting; yet there appears a strength and decision in the forms, a breadth in the parts, a facility of hand, and firmness of drawing, which point to their source in the Athenian school. This noble monument, erected by the senate and people, shadowy names! in the commencement of the second century, exhibits the greatest, as it was among the last efforts, of the true Greek school in Italy.

With the reign of Hadrian in the seventeenth year of the second century is introduced a new style of sculpture. From this date commences Roman art, properly so called, the distinguishing characteristic of which is extreme minuteness of finish, in this respect differing widely from the genius of the preceding century. Writers on the subject seem to have overlooked, or not to have been acquainted with this fact, and have described the distinctive peculiarity of Hadrian's age as belonging to the arts of the empire generally. There are, as already hinted, two eras in the history of sculpture in ancient Italy. Boldness of general effect, without the Grecian delicacy and exquisite skill in the detail, characterize the art under the early Cæsars. The second stage of decline we have now reached; when, seeking to recover the varied harmony of parts, the correct, yet grand details of ancient masters, but ignorant of their scheme and method of study, the Roman artists fell into the dry, the languid, and minute. In a falling art, while the greatest master-pieces had long been produced, and consequently, where imitation only could be the highest praise of the best, this path necessarily conducted to feebleness, imbecility, and final extinction.

Under Hadrian, however, this extreme is yet distant, the downward inclination only is more decisively given. The admiration of this emperor, otherwise possessed of taste, and some knowledge of art, for imitations of Egyptian sculpture proved directly adverse to the recovery of a free and generous manner. In the sculpture of this period every thing indicates the labour rather of the hand than of the mind. The design is borrowed, the execution is painfully original—the chisel—the file—the drill have been plied with ceaseless care, and with great mechanical dexterity. The hair in particular is often finished with a most wonderful address, as are likewise the eye-brows, which are more elevated than in works of a better age. The pupil of the eye is marked by a deeply drilled orifice, a peculiarity by which a work of this period may certainly be distinguished from all earlier performances. Over the whole genius and spirit of the art is now diffused an air of research, of studied, and even affected refinement, which smooths away every characteristic and natural expression. Hence in the contours of the head, and features of the countenance, though the separate parts be diligently rendered, and even more deeply marked than in more happy times; yet the principle of life, the exhibition of mind and soul, is wanting. For the sublime is substituted the difficult; for the elegant the florid; in short, sculpture abundantly proclaims the taste which preferred Antimachus to Homer, Dionysius and Favorinus to Demosthenes and Cicero.

The state of art under Hadrian, indeed, illustrates in a forcible manner our former remarks on the influence of individual patronage. His was a mind, active, not great, desirous of knowledge, without the grasp required for extensive acquisition; a taste capricious rather than refined, an imagination imitative, scarcely original, since the limit of his conception was to bring home more directly to the feelings, habits and national taste of his Roman subjects, those arts which they had been content hitherto to cultivate as exotics. Thus, the character of the prince, is exactly that of the genius of his age. Nor could it be otherwise in the arts, for however liberal to writers, to artists he proved an imperious dictator or envious detractor; painter, sculptor, architect, he could "bear no rival near the throne," who was not the creature of his will. Apollodorus, the favourite of his predecessor, paid with life the opposition which he ventured to make to some plan of a temple proposed by this "imperial mimic of old Egypt's piles." Yet has it been maintained that despotism is the clime genial to the arts! Let us not, however, be unjust; the remains of this age exhibit in some instances no mean beauties, and are among the latest relics of ancient elegance.

The reign and disposition of the Antonines were very favourable to the exercise, if not invigorating to the style of sculpture. Vigour, indeed, could not be restored, and the splendour was but a temporary dispersion of the darkness fast closing around the horizon of ancient greatness. Beyond this period, indeed, we need hardly carry our inquiries. How rapidly the arts had degenerated is evident on comparing the historical column of Trajan with that of Antoninus Pius, or more properly of Aurelius. Both are constructed in the same manner, the latter being composed of twenty-eight stones, and though of greater diameter, nearly of equal height, but in every respect indicative of talent the sculpture is greatly inferior. The equestrian statue of Marcus Aurelius is indeed one of the noblest monuments of antiquity, and shows deficiency neither of talent nor resource, but not possessing the means of comparison with any similar work, we cannot ascertain the comparative state of art. The busts of this period, especially the portraits of Marcus Aurelius, and Lucius Verus, are examples of the minute finish now constituting the highest excellence which the genius of the age was capable of producing or of appreciating. Throughout the course of the succeeding reigns this character varies only in its accessions of cold and unmeaning laboriousness. Under Severus a singular fancy arose of marking the countenance, especially the forehead, with deep furrows, adding still greater rigidity, with a yet more decided retrogression of redeeming excellence. Indeed it is hardly possible to conceive more rapid decay in all the remaining qualities of higher art, than must have taken place between the execution of the bronze equestrian statue of Aurelius, now in the capitol, and that of the sculptures on the arch of Severus, half buried amid the ruins of the Forum. The difference is yet greater, because the interval is longer and the inferiority more lamentable, in the bas reliefs on the arch of Constantine, that is, those of the same date, and not carried off from more ancient buildings, as compared with those on the arch of Severus. Beyond Constantine it would be vain to trace the progress of sculpture. Even the building of the eastern capital imparted no revived energies: for although the shell was the work of the age, as also the grosser ornaments, the plundered cities of Europe and of Asia supplied the only precious evidence of refined embellishment. Succeeding emperors pursued the same path, yet some degree of intelligence in art still continued, even to the fall of the empire; but to explore its results, would prove at once a melancholy and profitless exercise.

PART II.

MODERN SCULPTURE.

In the preceding columns we have traced the history of ancient art till genius appeared no longer to animate its efforts. It is not intended to assert that art itself became extinct; it is impossible to conceive the existence of a people, rich and luxurious, among whom the fine arts to a certain degree had ceased to be cultivated. But when in Italy an imperial master of the world is found pilfering from the virtuous record of a predecessor a few ornaments to adorn the tribute of their applause or of their flattery, which the living talents of his subjects could not supply—when her own matchless speech ceased to be understood in Greece—the ancient annals of human improvement might, as appeared, be closed. Long, dreary, and void is the darkness which must elapse before the books can be again unsealed in light. Still the human spirit was at work; the stroke of sculpture, rudely directed indeed, might be heard feebly sounding through the gloom; the pencil yet traced its barbarous mimicry on the chapel and the palace: the legend of the monk, the learning of the cell, filled the seats where philosophy and the muses once presided. In the west a series of monuments in Italy and Sicily enable us to trace the vitality, if not the progress of art, from Sylla to Nicholas of Pisa. In the east, the collections of the Byzantine historians, and even the remains now existing in Constantinople, prove a similar fact. The literature of the middle ages evinces, in both empires, the activity of imagination if not of judgment. The preservation of the classic monuments exhibits also a degree of taste, incompatible with the supposition of those ages possessing no arts of their own. In the commencement of the twelfth century, or even later, many of the master pieces of Greek sculpture, transported to the eastern capital by Constantine and his successors, were to be seen uninjured; they just caught to reflect for a moment the first ray of returning intelligence, then sunk for ever. To restrict our remarks to the subject under review, in the provinces of the west, the kindred studies of sculpture and architecture preserved throughout the lapse of those ages emphatically termed dark, some degree of reputation. The gloomy magnificence of the feudal baron, as formerly the polished elegance of the Roman patrician depended on their aid. Accordingly, in the monuments of those Italian cities, as Naples, Pisa, Siena, Venice, whose antiquities unite, as it were, ancient with modern history, we trace an almost continuous cultivation of those arts. An attempt, however, to record and to arrange the scattered evidences, unknown names, or probable conjectures, with which this space might be filled up, would neither be wise nor entertaining. We pass at once then from the age of Constantine to the revival of arts and letters in the Italian republics. In rapidly sketching the history of modern sculpture, our chief attention is commanded by the genius of Italy, on which the greatest artists of other nations must be content to appear as attendant stars. Our subject will readily admit of the following division. I. Revival of the art, including the sculptors from the 12th to the termination of the 15th century. II. Perfection—Michael Angelo and his school. III. Decline—Bernini and his followers. IV. Restoration—Canova and his contemporaries.

SECTION I.

From the preliminary remarks, it will appear that the extinction of the arts in the west has been assumed improperly as total. Their revival has in like manner been too exclusively ascribed to resources derived from the east. From various causes of partial judgment, the two grand events which in succession changed both the political and intellectual aspect of western Europe, the invasion of the empire by the Goths, and the fall of Constantinople, have been represented as exercising immediate and decisive influence on art. The occupation of Italy by the barbarous warriors who overthrew the Roman power, was followed, it is said, by the total destruction both of the monuments and the knowledge of learning and refinement. On the other hand, the reappearance of the arts in the twelfth, and their splendour in the fifteenth century, have been attributed, the former to an occasional influx of Greek artists, the latter to the misfortunes of the eastern capital, whose natives, seeking protection in Italy, enlightened the country of their exile.

It may be shown, however, in opposition to the former of these opinions, that in Italy neither the monuments of ancient taste were destroyed, nor the remains of living science exterminated by her conquerors; and that, in the various principalities into which this country was separated, the arts were never entirely forgotten, but, on the contrary, were cultivated, and by natives. The conquerors of this fairest portion of the empire were less ignorant and brutal than those by whom the distant provinces were finally occupied. They had been reared in the armies of Rome—they spoke her language—they venerated her grandeur. When the fury of contest had passed, therefore, when conquest was secure, they were more disposed to encourage than to suppress the useful arts, or elegant studies of their more cultivated, but unwarlike subjects. These acquirements in fact added to their splendour; and the earliest erections of the Gothic chiefs are evident though rude imitations of works of the Cæsars. Of these princes also we have still remaining several mandates prohibiting the destruction of ancient buildings, and offering encouragement to those who could repair or imitate them. Of these efforts in architecture and in sculpture, for these arts were inseparable, a series we have stated might easily be selected, uniting the reign of the last of the emperors with the establishment of the first of the modern republics. That these essays, such as they are, were the productions of native Italians, the names of the architects or sculptors, Bonani, Diotisalvi, Antelami, Beduini, Gramonti, Viligelmi, and many others, all living previous to the twelfth century, furnish evidence.

In regard to the latter assertion that Italy borrowed her reviving arts from the rival capital, it appears that so far from advancing the progress of western art, Constantinople could send forth no artists superior to those who flourished in the same age in Italy. During the thirteenth and fourteenth century, Dante, Petrarch, Boccacio, in energy of intellect far transcend any name which adorns the eastern empire: the country which could produce and relish these had surely nothing to fear from a rivalry in talent. Still more to our present purpose a more numerous and ingenious population, greater and more useful industry animated the Italian republics of this era, than were contained within the pale of the byzantine empire. The fall of its capital so far from advancing the progress of western art, took place after many of the happiest efforts of modern genius had already been accomplished. Sculpture had created works which have since been declared worthy of paradise; architecture had reared on the banks of the Arno the first dome of modern times—the exemplar of that edifice the most majestic ever reared by human skill.

Is there then no source whence we may derive modern sculpture at once consistent with the veracity of history, with the philosophy of art itself, and with the condition of mankind? Revolutions or improvements which deeply and permanently affect the habits or character of a people can be promoted by great internal changes only. For such then we must search in the present instance, and shall be able to discover another proof of the constant intimacy existing between the social happiness, the moral dignity of man, and his progress in refinement.

The subjugation of the western empire might have proved an event in the highest degree fortunate for Europe. In every part of the Roman dominion the powers of genius, moral worth, social virtue, all that dignifies man's nature, had long rapidly declined. The engrafting then of the rude but honest virtues and energetic character of their conquerors upon the refinement that yet remained to the Italians, would have wrought a material improvement. A new impulse would have been given, and civilization would have recommenced as from a new era. Unhappily for this reciprocal melioration, throughout the wide extent of these conquests, the feudal government was uniformly established; than which no system could be more directly opposed to individual happiness or general improvement among the people. The affections and the energies of the human heart were alike benumbed where the human race acknowledged the sole relation of tyrant and slave, or its sympathies were roused only in deeds of violence and of lawless power. A deathlike depression overspread the empire of intelligence. Some vital change could alone break the dismal solitude of the mind, and restore its nobler faculties to activity. Accordingly, when about the commencement of the eleventh century, the cities of Italy threw off the the yoke of feodality, and proclaimed themselves independent, the sound of liberty broke the unhallowed calm—the waters were moved—the healing influence was shed abroad—cleansing from mental degradation and political debasement. In the train of freedom sculpture and the arts appeared among the earliest attendants. The moral history of these republican cities presents indeed an agreeable and brilliant contrast to their political annals. The latter exhibit a fearful record of the turbulence, vacillation, and injustice of popular authority and licentious liberty. In the former are strongly illustrated by their effects, those generous and dignified principles of legislation, which originate not in artificial systems, but in the heart and constitution of man—which interest the noblest feelings in defence of the dearest rights.

The arts, as moral causes of powerful efficacy, and as pursuits of general concern, were from the first cultivated with ardour. Their labours, especially those of sculpture, were, from the earliest, dedicated to the service of religion; next exercised on public works, uniting utility with magnificence; and finally, consecrated to embalm the memory of patriotic deeds and virtuous characters. While his acquirements were thus prized, the intelligent artist was honoured as the ornament of his country. Reciprocal sympathies thus gave and received inspiration.

Among the republics of Italy, Venice earliest succeeded in fully establishing liberty; Pisa, however, took the lead in founding a school of native art. Early in the eleventh century, (1016), her cathedral was begun, the ornaments of which were composed chiefly of fragments of Greek sculpture, relievos, capitals, and even whole columns, which the eastern commerce of the Pisans enabled them to procure, and which proved most valuable in the renovation of taste, as both exciting emulation and supplying models. This great building was conducted by Boschetto, the first architect and sculptor of eminence in Italy; but the incorrect reading, from a fracture in the tablet, of an inscription at Pisa has deprived her of the honour of having given birth to this founder of modern art, who has thence unjustly been recorded as a native of Dulichium.

Of the numerous schools thus established at Pisa, the most distinguished members afterwards became celebrated by their works in various of the surrounding cities. But the reputation of these has been forgotten in the superior merits of Nicolo Pisano, the glory of the twelfth century, and under whom sculpture first assumes dignity and importance. He early attached himself to the study of antiquity, having remarked the striking difference between the labours of Boschetto and fragments which had been brought from Greece. It was from the latter he formed his style; and in his works we often trace a very marked resemblance to the character and manner of some remains still preserved in the cathedral or in the *Campo Santo*. His principal works are the pulpits of Siena and Pisa, the beautiful bas relief on the façade of the cathedrals of Orvietto and Lucca, &c. But it is a species of injustice to particularize: the influence of the genius of Nicolo is to be traced in every building in Italy of this era; as also the authors of minor works of art, as chapels, altars, tombs, fountains, relievos, must be ranked as pupils either immediately or remotely of this school. Of the former class the most eminent were Giovanni, the son of Nicolo, and two strangers, brothers, of Siena, Augustine and Angelo.

With these the science of their master did not languish, as may still be seen in the cathedral of Siena, one of the finest in Italy, of which the three were the joint architects. In this erection we first read of sculpture being admitted as a separate profession; and there are still preserved the original rules and regulations of a confraternity of sixty-four sculptors, then first incorporated. The style of Giovanni however, was considerably diversified from that of his father, his outline being more flowing, his drapery broader and less determined in the folds, and his whole composition more soft and delicate. This artist exerted a degree of influence over the arts not only of his native country, but of the whole of Europe where art was known. Even in England in the sculptures prior to Henry VII., as in the monuments of Queen Eleanor, it has been thought that the style, if not the very designs, of Giovanni have been discovered.

Before the end of the thirteenth century the cities of Etruria, the ancient seats of the arts, had already made progress in the study of sculpture. Florence, destined afterwards to become so conspicuous, had not yet from domestic feuds been able to distinguish herself in the arts of peace. When the attention of her citizens was at length directed to the study of elegance, painting at first obtained the preference. Cimabue, born in 1211, received the rudiments of a barbarous art from some Greek painters who were employed at Florence; he quickly surpassed his instructors, and was himself excelled by his own pupil Giotto, whom he had taken up a shepherd boy in the vale of Arno. Andrea da Pisa, the grandson of Nicole, was, about the commencement of the fourteenth century, invited to Florence, and thus became the father of Tuscan sculpture. The works of this artist, the relievos of the Campanile, and the bronze folding doors of the Baptistry, still proclaim his merits; while his sons, Tomasso and Nino, sustained the reputation of their instructor, and by their pupils widely disseminated the art over Lombardy, Venice, and the south of Italy. The primitive school of Pisa is thus the true source of modern art, for Venice was at first occasionally assisted by artists from the east, and subsequently from Tuscany. The grand political and moral causes which operated so powerfully in other states, were there comparatively feeble in their effects. Her proud and exclusive aristocracy rather converted the arts to the purposes of private magnificence than employed them in the service of national greatness. It was this union of the arts with national feeling, while the freshness of newly acquired liberty gave to that sentiment energy and vigour, which so eminently conduced to their progress in Italy. Her free cities had thus advanced in the acquisition of elegant taste, for in 1350 was established the first academy of design in Florence, at least two centuries before the rest of Europe had started in the career.

The fourteenth century closes the infancy of sculpture; of this period the principal works are relievos; statues are few in number, and generally inferior in workmanship. The former are to be regarded among those performances and discoveries of one age, which immediately conduct to the improvement and superiority of the succeeding. Thus the relievos on the altars and tombs in the different cities of Tuscany, and of the Tarlati and Scaligers at Verona; the pulpits of Pisa and Siena; the bas reliefs on the cathedral of Orvietto; the decorations of St. Mark's at Venice and the Ducal palace; the sculpture of the Belfry at Florence, above all the bronze folding doors of the Baptistry,—constitute the intermediate gradations while genius was emerging from the barbarism of the dark ages, presenting the steps by which it ascended to the eminence of the two following centuries.

As respects the style of art during these early ages, we find that from the time of Nicholas of Pisa, whose views are frequently drawn from antiquity, a general character of simplicity, of fidelity, and of just expression, begins to appear in sculpture. The mind is never astonished by boldness of execution, or grandeur of composition; but the art being chiefly dedicated to the service of religion, or to the memory of the dead, there is often in its best labours an air of devotional sincerity, a touching representation of the gentler affections, which soften the heart and awaken the sensibility. The effect is never daringly ventured; it is sought by force of labour—by persevering discovery, rather than produced by any acknowledged principles of taste or rules of design. But if the creative faculties have seldom been conspicuously exerted, we are sometimes agreeably surprised by unexpected beauties of the sweetest power arising from a diligent imitation of nature, which give back the image of the original in all its simple and unpretending reality.

The fifteenth century forms a splendid era in the progress of intelligence. Advances in moral, intellectual, and political knowledge were then accomplished, which form the groundwork of no small portion of modern science. In the arts of elegance, especially in sculpture, the labours of this age will always hold distinguished rank. During this interval, love of liberty and of information animated the Italian republics. As if there had also been a commonwealth of talent, no single master so far excelled his contemporaries as to impress upon the art the stamp and bearing of an individual style. The very opening of the century presents the friendly contest of six great masters, competitors for the same public work, who had been selected from a still greater number of candidates. Brunelleschi and Ghiberti, Florentines, Jacomo della Quercia of Siena, Nicolo Lamberti of Arezzo, Francisco di Valdambrino a Tuscan, Simone dei Colli, were the artists thus chosen to compete for the honour of executing the bronze folding doors of the baptistry. After a year's trial, in which each produced a pannel of the proposed work, representing the sacrifice of Abraham, the specimen of Ghiberti was preferred. The undertaking thus honourably assigned to his superior merit, occupied forty years of his life, still remaining one of the noblest monuments of modern art, and declared by Michael Angelo worthy to be the gate of Paradise. The subjects of the one are taken from the Old, and of the other from the New Testament.

Of the other candidates, Brunelleschi afterwards applied chiefly to architecture; the remaining four, by their works and the merits of their schools, widely extended and improved the art. Among the crowd of illustrious contemporaries, Donatello, born in 1403, stands forth pre-eminently conspicuous by the magnitude and excellence of his labours. These are in almost every material capable of receiving the impress of his chisel, and dispersed throughout the principal cities of Italy. The best are in Florence; among these the statues of St. George, Magdalen penitent, and St. John, are fine examples of grandeur, simplicity, and truth, in composition and expression; while the equestrian statue of Erasmus duke of Narni, in that city, claims notice as the first attempt in the revival of art. But the great superiority of this sculptor is chiefly remarkable in relievos, a department of the art which in the course of this century acquired a degree of perfection that yet remains unsurpassed: nor does it appear easily possible to excel the beauty of those in the church of San Lorenzo, in which this master has represented the most memorable events in the life of the Saviour. The subject seems to have imparted to the genius of the sculptor a portion of its own sacred dignity—of calm and holy feeling. Indeed, to the influence of religious impressions we attribute in no small degree that improvement so conspicuous in this age, the principal exertions of which were directed to the representation of Scripture history.

The scholars of Donatello were very numerous, for he may be said to have founded schools in the leading cities of Italy; they may be divided into two classes. The first comprehends those who, without producing much of what was original, have attained reputation as co-labourers in the most considerable undertakings of their master; such as Simon his brother, Giovanni da Pisa the second of the name, Bartoldo, and William of Padua, who travelled into England. The second division of the school of Donatello consists of his true disciples, who, not servilely following in his train, preserved, or even improved the science of their instructor. These include many of the leading masters of the time—as at Florence, Michelozzi, famous in bronzes—Settignano, whose sculptures are graceful and lovely—the two Russilini, the elder of whom was the first architect of St. Peter's. In Bologna, Modena, Lombardy, Naples, were scions of the same school; in the last were especially distinguished the two Massicii, Monaco, Cicione and Fiore. Of the Venetian school, the ornaments were Riccio, who wrought exclusively in bronze, Cavino and Leopardi, scholars also of Donatello. This great artist died in 1466, having survived his rival Ghiberti about eleven years. For nearly three quarters of the century, these two masters presided over sculpture, nor has the lapse of successive centuries diminished their just claims to estimation: both excelled in relievos; and Donatello in high, Ghiberti in low relief, have produced models yet unsurpassed—seldom equalled. The influence of the former on the art universally was the more direct and extensive: but the talents of neither claim such pre-eminence as to obscure the merits of contemporaries, or of immediate successors. Improvement was more the effect of general talent than of individual superiority. After their demise, the art was far from languishing in the hands of Luca Della Robbia, Briosco, Lotto the first repairer of the antique—of the Majani, eminent in sculpture and Mosaic—of the Pallajoli, painters and sulptors, instrumental in the introduction of anatomical science—or of Andrea Verrochio, undoubtedly the greatest master at the close of this century—while towards its close in the academy of the Medici are to be found Pietro Perugino—Leonardo da Vinci—and more illustrious still, Michael Angelo.

From the Alps to the shores of Calabria sculpture was thus cultivated with eminent success, while in the other states of Europe the arts still slumbered, or merit not particular examination. Florence was the central point of refinement, where is to be observed most full development of principle with greatest freedom of execution. Assuming the best works as exhibiting the real extent to which science had attained during this period, we find the style and character of art to be in a high degree elevated as well as pleasing. The simplicity is refined, remote alike from affectation and poverty, the skill is great, but never exercised to astonish or surprise: nature is imitated with fidelity and by the simplest means; the manner never allures from the subject, so that the work is long admired before it occurs to inquire whence the fascination arises. The great proportion of sculpture of the fifteenth century is in bronze, a circumstance which may account for the style of execution minute and delicate, but frequently unenergetic and restrained. As respects intellectual merits, the style of design is always chaste, often extremely elegant; the composition judicious and unaffected, seldom strongly marked; the expression sweet and calmly dignified, for rarely is strongly marked passion attempted. We observe no decided aims at representation of abstract beauty; the powers of fancy are never presumed upon, and seldom roused; but the mind of the artist, now no longer wholly occupied in mechanical detail, selects and combines; if the forms and manners are not invested with ideal elevation, the most perfect models of real existence are not unsuccessfully imitated. Were the extent or object of art confined to the simple representation of nature, sculpture would now verge on perfection. But, by the genius of the sixteenth century, there yet remained to be added greater ease and grace of execution, more forceful and elevated expression, more refined selection of form, and more of those charms which imagination lends to reality

SECTION II.

The sixteenth century, in its commencement, discloses a state of things highly favourable to the advancement of Sculpture. In Italy—yet the only seat of art, refinement had been widely diffused; learning was esteemed, freedom and opulence reigned in the republican cities: princes and nobles generally showed attachment to elegant splendour, and were emulous in patronising merit, whether in arts or letters; while, above all, energy and activity were the characteristics of the age pervading every rank. The advanced condition of their attachments enabled sculptors to derive every advantage from these external causes. A new field likewise was then opened for their exertions. To maintain that universal sway to which the papal sovereigns had constantly aspired—spiritual weapons and temporal power had in succession been employed; the progress of knowledge had dispelled the terrors by detecting the unhallowed nature of the former, and the temper of the times was no longer disposed to bend before the latter. Means of empire, more congenial to the minds of living men were to be essayed; it was resolved to constitute to Rome the metropolis of religion and of art; to consecrate her monuments by devotion and by taste.

To carry into effect the mighty undertakings, the greatest in modern ages, to which this design gave birth, Michael Angelo arose. As the splendid resolves of Pericles to render Athens the abode of ancient refinement would have proved vain without the talents of Phidias, so the energy of Julius, or the elegance of Leo, would not have availed, unaided by the mind of Buonaroti. The times, the men, the objects and the consequences, bear a striking resemblance in both cases. As the Greek commanded our chief attention in classic art, so, from the labours and genius of the Tuscan, we derive the truest estimate of the best age in modern sculpture. The former, however, asserted the assigned pre-eminence by the intrinsic merits and beauty of his productions: the latter arrests our regard, not so much from the perfection of his works, as from having left the impress of an irregular though mighty spirit upon his own and the succeeding ages. When the attainments of Michael Angelo are collectively considered, when in the same individual is discovered the architect of the Cupola—the painter of the Last Judgment—the sculptor of the Moses, discriminating qualities are lost in general admiration; and to him who thus bears away the palm of universal talent, we are inclined to concede the foremost rank in each separate pursuit. For nearly three-fourths of a century he was acknowledged also as the head alternately of the schools of Florence, Rome, and Venice. When this pre-eminence was first assumed, painting was in infancy; the feeble attempts of his master, Ghirlandajo, were viewed with wonder, and only in the frescoes of the unhappy Massaccio, had any indications of an elevated style previously appeared. The cartoons of the battle of Pisa, and other works of Michael Angelo, appearing under these circumstances, suddenly raised the art to strength, boldness, and scientific correctness; to that sublimity which formed Raphael and his compeers. In architecture, though at a later date, St. Peter's stood, and still stands, alone, unequalled—

> Yes thou, of temples old or altars new,
> Standest alone. With nothing like to thee—
> Worthiest of God, the holy and the true.
> Since Zion's desolation, when that He
> Forsook his former city, what could be.
> Of earthly structures, in his honour piled
> Of a sublimer aspect? Majesty,
> Power, glory, strength, and beauty there are aisled.

In sculpture, such superiority could not be attained; here great excellence had already been achieved, in some respects little remained to be added, nor are the additions always improvements. But the style of the fifteenth century, exquisite in unaffected simplicity, was not adapted to please in the succeeding age, and under a system of refinement, when the forcible and the imaginative were admired in preference to the simple and the true. The works of Buonaroti at first created and subsequently fostered this taste. His sculptures were erected into a standard, according to which earlier masters were to be estimated, and by which future artists were to direct their aspirings. The past thus appeared tame and lifeless, while contemporaries and successors constrained to become imitators, successively remained inferiors, where laws were thus received from the prestiges of an individual mind. The character of that mind, indeed, elevated sculpture; but round a false, though gorgeous and imposing art, genius swept a magic circle, within whose perilous bound none else durst walk—and where the mighty spirit still reposes in self-created superiority—in awful and unshared solitude.

Hence as a sculptor, the fame and excellence of this artist have been exaggerated. His works are far from numerous, and even of these few are finished. His undertakings were gigantic—his activity indomitable—his daring boundless, but impatience of slowly progressive labour, or fastidiousness of fancy, formed striking distinctions in his intellectual temperament. In these works, scattered throughout Italy, and found even in France, two styles have been supposed to be discovered; or at least in his earlier years their author is presumed to have followed a distinct set of principles from those which guided his maturer judgment. A gradual departure, it is said, may be traced from the simple and the natural towards the exaggerated; and two classes of his sculptures have been made accordingly—a position thus illustrated by a learned and elegant writer on the arts. *Una donna che accostomarsi giovinetta a lisciarsi le guacie di minio non passano molt' anni che senza avvedersene le pare d'essere sparuta se non mostrarsi colorita come una maschera scenica.* That diversity of style is to be detected, we admit; but after a careful examination of every original, except two unfinished statues, said to be in France, we are inclined to discredit the existence of any regular progression. The Pietà, or Virgin and dead Saviour, is at once the last, the most finished, and the least exaggerated group of the author; and so far from being insensible of the peculiar characteristics of his style, he lamented them, and predicted at the close of life the fall which he had thus prepared for the art.

The works of Michael Angelo are now divided between Florence and Rome. In sculpture, each contains a master-piece; the tombs of the Medici in the former, and the unfinished sepulchre of Julius in the latter city. To this belongs the Moses—a record of genius isolated and rendered unavailing in art by the peculiar nature of its own especial sublimity. But without entering minutely into description, we shall state generally the impress left on the mind, and the influence exerted upon the arts by the genius of this extraordinary man.

The sculpture of Michael Angelo discovers much that is derived from a liberal and enlightened study of sublime and graceful nature; but still more of those qualities which arise from the peculiarities of an individual, though rich and powerful imagination. His studies rarely exhibit the simplicity and repose essential to the character of an art—grave, dignified, or even austere, and possessing means comparatively limited and uniform. But forced and constrained attitude, exaggerated proportions, unnatural expression, are redeemed by a force, an energy, an enthusiasm elsewhere unfelt, which give to every composition a vitality and power resembling rather the effect of inspiration than of reiterated and laborious effort. Neither with nature nor with the antique can his works be rightly compared. They stand isolated by a peculiar sublimity of conception, the matchless monuments of a daring spirit forcing present admiration in despite of calmer judgment. The first impressions are thus irresistibly powerful, but they are those of surprise, of astonishment, not of delight or of sympathy. The fascination is thus quickly dispelled, the mind reluctantly yielding to an influence, originating solely in the imagination, and in which the sensibility has no portion.

The ideal of Michael Angelo indeed, is constituted entirely of the imaginative. His sublimity is sought too exclusively in the vehement and the marvellous. His design, expression, forms, and attitudes, have little communion with nature, at least with nature in her solemn majesty—her dignified repose—her unpretending simplicity, or in those her milder beauties, which sentiment and feeling appreciate. The perfection of art, as displayed in the works before us, appears to have been placed in embodying the wildest, the most gloomy, the severest, and most awful imaginings of the mind, under shapes the most masculine and energetic; and in positions the most difficult or uncommon. Both in conception and in execution Buonaroti has created a style adapted to display his own powers, but which could be supported by these alone. With him the arts were not imitative, but creative. Compared with themselves his productions are astonishing evidences of human power: tried by nature's rules, they are ever remote from reality, not seldom irregular and fantastical. Every thought exhibits the impress of a mind delighting in the grand and the wonderful—eager in the pursuit of untried modes of existence, and conscious of powers to execute the most daring conceptions. This gives to his ideal more of the vague, but soul stirring enthusiasm which belongs to poetry, than of that sober inspiration and steady imagery which direct the judgment and guide the practice of the sculptor. His execution participates largely in this unquiet and aspiring character of composition. It is rapid and fervent, but inaccurate in minor details, and too prominent in general effect. Intelligence in the naked, breadth of touch, boldness of manner, give the very effect of life and movement; but to a display of science, simplicity, and even truth, have been sacrificed. Difficulties seem to have been courted in order to be surmounted with address; the attitudes are consequently the most remote from such as would voluntarily be assumed, or graceful design select; they are in a high degree constrained, and from an undue exhibition of knowledge—the pedantry of art in rendering them, the forms have more the appearance of anatomical studies than the warm full figures of life. The general character of this style then is every thing but natural; art stands forth boldly prominent, challenging admiration, not as a means perfect as it eludes regard, but as a final end, claiming in itself a distinct and paramount excellence, independent of nature or of imitation, and exhibiting its creations as evidence of separate origin,

"Like life, but not like mortal life to view."

The death of Michael Angelo, in 1564, created a blank in the history of art, which never has and never can be filled; but in the principles of the art itself, in those principles which he himself had introduced, the event caused no change, save that their ministration passed into feebler hands. During his lifetime, the sculptors of this era, however various in talent, may be classed as his disciples; for though many approach, and one or two even excel in some quality, yet they rest generally inferior, while the character and manner of their productions but reflect the style he had invented. Still, among his contemporaries, we are to distinguish between imitators merely, and pupils, properly so termed.

Baccio Bandinelli, born at Florence in 1487, was the enemy rather than the rival or imitator of Buonaroti; there is yet a strong resemblance in their manner, allowing for general inferiority in the first, with a similar display of exaggerated science; although in some instances, Bandinelli exceeds in softness and delicacy. But this is not the general character of his works, which exhibit strength without regularity or refinement. Baccio di Monte Lupo was also an original artist of considerable eminence, as is still attested by his best performance, the crucifix in the church of San Lorenzo. Andrew Contucci, founder of the school of Loretto, whence many excellent works then issued, is an imitator of Michael Angelo, with no mean additions of his own. Francisco Rustici, eminent as a founder, pupil of Leonardo da Vinci, carried the manner of this school into France, and died in Paris in 1550. During the early part of this century, Giacomo Tatti or more popularly Sansovino, presided over the Venetian school with much reputation. The magnificent range of the Piazza di San Marco, is of his erection. His style of sculpture is distinguished for richness of composition, but is deficient in purity; and though decidedly founded on that of the Tuscan, whose principles Sansovino had studied at Rome, whence he fled on the sack of that capital by Bourbon in 1527, it displays greater softness, with less of vigour and originality. He survived his master, and was the head of a numerous school, of which Danese Cattaneo and Alexandro Vittoria were the chief ornaments, the one in arts and letters, the other in having perfected the useful practice of working in stucco. In Lombardy and in Naples, similar principles were followed, and with scarcely unequal success; or, in these schools, the less valuable peculiarities of rapid execution and exuberant fancy were cultivated in preference to learned design or accuracy of taste, from the splendour of the respective courts demanding the employment of the arts on objects of temporary interest. In Milan, however, Agostino Busti, and especially Guglielmo della Porta, whose statues of justice and prudence on the tomb of Paul III. in St. Peter's have been admitted among the best examples of modern sculpture, were highly esteemed; as also in Naples, were Marliano Nola and Girolamo St. Croce.

Among the real disciples of the great Tuscan master, the following may be mentioned as the principal:—Raphael di Monte Lupo, a favourite pupil, by whom are the two statues of the Virtues on each side of the Moses in the tomb of Julius II.: Nicolo di Tribulo, an excellent founder, author of the fine bronze-gates of the cathedral at Bologna: Giovanni dell Opera, whose name attests his prolific genius, and who had the honour of placing the statue of architecture on the tomb of his instructor; where in Florence

In Santa Croce's holy precincts lie
Ashes which make it holier—dust which is
Even in itself an immortality.
——————— here repose,
Angelo's Alfieri's bones, and his
The starry Galileo with his woes.

——— "Beata che in un tempio accolte
Serbi le Italie glorie—ultime forse.

Vicinzo Danti closely and not unequally imitates the style and manner of his master, as attested by the group of victory chaining a captive in the old Ducal palace, being ascribed to him, though the most intelligent judges assign it to the latter, as one even of his most vigorous thoughts. Michael Angelo certainly did retouch this still unfinished piece; and tradition rightly attributes to his crayon the lines in red chalk visible on the back and shoulders of the figure, where reduction seemed to be required. Bartolomeo Ammanati first studied sculpture with some success, but subsequently transferred his attention to architecture, in which he became eminent. Benvenuti Cellini, a man of the most versatile powers; his works of sculpture are in metal, of which the Perseus and the Mercury, poised on one foot, are the principal. But the greatest of this school still remains to be mentioned, Giovanni di Bologna, a Frenchman by birth, an Italian as a sculptor, who, from the magnitude and number of his productions, from the beauty of his style, and the excellence of his genius, approaches nearest to his master. To the end of the sixteenth century, this artist occupies the prominent place in the history of sculpture; he terminated the series of illustrious names of that era, and his last great work, the group of Hercules and the Centaur, erected in 1600, closed the Tuscan school for ever. In examining his performances, we ascertain those advances which were accomplished during the last thirty years of this century, while the mantle of their great teacher still rested upon the favoured of the disciples; while yet the impetus derived from the mighty movement awakened by one mind had not spent its force. During this space we find the technical part considerably improved, operative art better understood, and its processes facilitated. Hence, though no preceding sculptor can show works more numerous or important, those of Giovanni di Bologna discover no marks of haste, no deficiency of a high, and even in some instances exquisite finish; it is even apparent, that many of the inaccuracies, into which a fervid and impatient spirit hurried his master, have been avoided.. Still in the works of the pupil, in their general style and manner, we observe the growing evils which the example of the instructor introduced, but which supreme genius consecrated or concealed—bold, rapid, and masterly execution—grand and imposing composition preferred to, and even excluding, delicacy of expression—attentive study of truth, and of those sweet and gracious sensibilities through which art becomes the "obvious, not apparent, but retiring" representative of nature—which elevate without startling the imagination.

Before leaving the subject of Italian sculpture during the sixteenth century, one name, closely connected with the general improvements of art during this interval, claims some notice, more especially as the merits of Leonardo da Vinci, one of the most venerable names of the age, seem to have been hardly estimated by the elegant historian of Leo X. On perusing the observations of Mr. Roscoe, the impressions, we think, which are left upon the mind regarding Leonardo, are, that he was a dabbler in various knowledge, but proficient in no one branch; a laborious trifler, who wasted in useless multiplicity—in chemistry, mechanics, and experimental philosophy, talents which ought to have rendered him great in art. We confess, however, that the manuscripts of Leonardo which we have seen in the Ambrosian library at Milan, give no mean opinion of his attainments, even in science, the times considered. If in art his productions be few, they are very precious; let it also be remembered that his cartoon of the battle of Pisa, drawn in conjunction with one by Michael Angelo, was not inferior, if it did not excel, and that these first exhibited true greatness of style in modern design. In relation then, to the remarks of the English historian, we join with count Cicognara, who concludes rather a severe criticism in the following words, *ci sembra troppo azardato e non mai dittato da quella matura circospezione che tanto distingue lo storico da noi indicato.* The common opinion respecting the "Last Supper" repeated by Mr. Roscoe, namely, that the artist was unable to represent the principal figure with a dignity superior to the others, and therefore, left the piece unfinished, is certainly erroneous. The mistake seems to have originated with Fra Bartolomeo of Siena, who, in a book entitled *de Vita et Moribus beati Stephani*, first relates the circumstance: but, before the appearance of this work, cardinal Frederico Borromeo in 1625, had published a little treatise expressly on this picture, in which he not only says nothing of the head of Christ being left unfinished, but actually praises the expression, *venerabile Salvatoris os altum animi mœrorem indicit, qui tamen gravissima moderatione occultatus atque suppressus intelligitur.* This little tract, from its rarity and the fine taste which it displays, is, by the Italians, termed, *Aureo Libretto.* To the other claims of Leonardo as one of the fathers of modern art, it may be added, that names, eminent both as painters and sculptors, received from him their knowledge of these branches. "Art," indeed, "is jealous," but at her shrine the devotion of da Vinci was neither without fervour nor unfruitful, although he courted, not unsuccessfully, the favours of science, then new to the mind. We trust an endeavour to reconcile these claims with the observations of a living historian whom we hold in high admiration, will be deemed neither improper in us nor irrelevant to the subject.

Beyond the confines of Italy, the art had yet made few advances worthy of notice; and what little had been effected was on the principles of the Tuscan school. In England, Spain, and Germany, during the sixteenth century, painting was patronised in preference to sculpture. Torregiano, the envious rival of Michael Angelo, had erected in Westminster Abbey the tomb of Henry VII., for which he received £1000, a very considerable sum at that time; but this turbulent spirit was inclined rather to brawl with, than to instruct the English in his art; and in the succeeding reigns we find Holbein and Zucchero in high favour; but hear little or nothing of sculptors, with the exception of John of Padua, who acted as master of works about the close of this century. In fact, in the early history of English art, anomalies of a singular nature are encountered. From the seventh to the fifteenth century, four distinct species of architecture may be traced in the sacred and feudal edifices of Britain. During the two succeeding centuries the art declines, nor till the reign of Charles I. is it revived with any degree of magnificence. Sculpture, in these early times, was exercised only as an ornamental branch of architecture, or in tombs; and in each, it is singlar that, taken generally, the sculpture of the thirteenth is superior to the art of the fourteenth or fifteenth century; that of the sixteenth exhibits evidences of Italian origin.

Bermudez, the Spanish historian of native artists, has given a splendid account of Sculptors from the sixteenth century upwards. The beautiful ecclesiastical edifices of Spain afforded an extensive field for sculptural ornament, and it is easy to perceive that those employed with a remarkable success in such embellishments have been exalted by national partiality to the rank of sculptors and artists. This opinion derives confirmation from the fact, that not till 1558 was sculpture, in consequence of a royal edict, allowed the privileges of a liberal profession. About this period Berruguete, after studying under Vasari and Buonaroti, returned to his native country, and at once exalted the arts of Spain to grace, beauty, and correctness. Previously, indeed, she had been indebted to Italy, and Torregiano in his wandering life, after residing and working for some time, had starved himself in the prisons of the inquisition to escape a horrible death, to which priestcraft and aristocratic insolence had unjustly condemned him. Berruguete, however, appears to have been the first native artist of Spain who acquired and deserved a high reputation; he founded a numerous school, of which Paul de Cespides was the ornament, perhaps the greatest of Spanish sculptors.

Before the seventeenth century, Germany makes no appearance in the history of sculpture. Both in letters and in art she has entered the field at the eleventh hour: in the former, her sons have already effected noble progress; and in the history or philosophy of the latter, what have we finer than the writings of Winklemann and Lessing? In practical art, however, the Germans are still deficient: nor, perhaps, is that metaphysical enthusiasm—that ideal aspiration by which their national genius is distinguished, well adapted to succeed in the energetic but laborious realities of sculpture. Or if they do obtain reputation, it will be in that department which forms the most precious portion of their poetry and painting—unadorned representations of sweet and simple nature. The past history of their arts supports this idea in some measure, although it is probable had their enlightenment been such as to enable them to meet the advances of the sixteenth century, the grand and the wonderful in the style of Michael Angelo, would, to the Germans, have possessed irresistible attractions.

In France, the expeditions of Charles VIII. but more especially the close connection between the two countries in the reign of Francis, together with the personal predilections of that monarch, tended to diffuse some knowledge of the arts of Italy. French writers have strained hard to elevate their native arts from an early date; and Jacques d'Angouleme is reported to have surpassed Michael Angelo himself in a trial of skill at Rome. Certain it is, that during the sixteenth century no artists out of Italy could have competed successfully with Jean Gougon, author of the celebrated fountain of the Innocents, finished in 1550. He was also an architect and engraver. Of his life little is known, except its termination in the massacre of St. Bartholomew's. Of all his countrymen and contemporaries, Jean Cousin possesses most grace and delicacy, but to the acquisition of these he has sacrificed strength and correctness. His works are still to be seen in several of the churches of Paris. German Pilon displays great energy and fire, with much beauty of mechanical detail; but his works are affected and destitute of natural expression. Indeed, from its origin we may trace an affected manner in French sculptors, which gives to the style even of these early masters a peculiar air of nationality, although it is evident that the principles in all other respects are derived from Italy. These artists in fact were all pupils, either mediately or directly, of the Tuscan school; and Giovanni de Bologna and Francavilla, both French by birth, filled the whole of France with the style and manner of Buonaroti.

During the sixteenth century, the most brilliant period in the history of modern sculpture, the genius of Michael Angelo thus dominated throughout Europe to the utmost capacity of her living arts. The character of that genius we have feebly endeavoured to estimate; and we fear, to indiscriminate admirers our estimate may not be deemed so favourable as the general voice proclaims. An explanation then of the principles on which we have formed our judgment, seems not uncalled for, nor of the standard with which his works have been compared. Irregularities in the productions of genius have not seldom been caused, and are extenuated by an idea too generally entertained, that to its genuine efforts no established modes of judging are applicable; in like manner, as rules are inefficient to create its presence. A power certainly resides in superior minds of being a law unto themselves, *petimus damusque vicissim*. This privilege of invention, however, or of departure from the more obvious relations of existence is limited according to the nature of the exercise; in poetry most excursive, in the imitative arts more restrained, and of these, sculpture admits the least deviation from reality; here truth is more especially the criterion of beauty, because its imitations are constituted of no illusive effects. The objects of this truth are in all the arts two—resemblance and consistency. The former respects the connection subsisting between the representation and the original: the latter regards the agreement of the composition with itself and with the peculiar mode of imitation. In the first case, art is compared with nature, in the second with itself, and in both sculpture is particularly circumscribed in its elements; in resemblance being restricted to form and expression, while, to be consistent, it must be grave, simple, and uniform. The practice of antiquity also, here exerts so paramount an influence, since the art so exclusively belongs to classic times, that it may be justly questioned how far any modern artist can improve by deviating from forms, which rest upon the intrinsic excellence of the examples, and on the prescriptive influence of opinions established long and felt universally. An authority thus neither local nor temporary, operates as a precept of immutable taste, as a sentiment of unchangeable feeling, and consequently assumes the certainty and importance of truth.

But from all of these principles, both of nature and of the antique, Buonaroti has departed. Nor can it with justice be urged, as is done in his favour, that his powers are too original—too mighty for subjection to these laws; that by no standard can we estimate, by no rules can we judge the most sublime, yet the most daring of modern artists, who hovers on the confines of possible existence, and in whose labours like contending light and darkness, grandeur, and extravagance are often blended. This would imply that he was above, because he was ignorant of the principles by which he has been tried. But than Michael Angelo few great names have more extensive obligation to preceding knowledge; he was acquainted with some of the finest specimens of antiquity, while his predecessors had left instances of beauty yet unexcelled. On what grounds then can we concede to this artist those privileges which Homer, Shakspeare, and others who like them have lived in ignorance of more perfect models, and in the infancy of their respective arts, can alone justly claim?

From the antique, Michael Angelo has deviated in one most important respect. Of the two elements of sculptural design—form and expression, the Greek artists selected form as the object of their imitation. The modern has preferred expression, to which we may say he has almost sacrificed form. To this, not only the force of associations springing from the most perfect of human productions was opposed, but the internal proprieties of the art favour the choice of the ancients. In sculpture all is staid, enduring, actual, movement alone is the only passing object of imitation. Expression, therefore, at least strong expression as the primary characteristic, both as destructive of symmetry, and as implying an effort ungraceful when connected with the unyielding materials, seems not a legitimate element of higher art. A sweetly-pleasing, a gentle agitating sentiment, or a nobly repressed feeling, is the genuine expression of sculpture.

From nature Michael Angelo has departed further, we will venture to say, than any great name on record, whether in literature or in art. Irregularities and imperfections in almost every other instance of lofty genius are forgotten amid the deep thrilling pathos or soothing loveliness of natural representation; but amid the awe-inspiring, the commanding, the overpowering creations of Buonaroti, the soul languishes for nature and simplicity. His forms are of superhuman energy—fit habitations of the fierce and resistless spirits that seem to dwell within; they are not of this world, nor does the heart respond to that interest which with mysterious mastery they exert over the mind; yet their power is confessed—the power of art and imagination. This great sculptor had marked the perplexities and the constraint under which, amid their fidelity and affecting expression, his predecessors had visibly laboured in their endeavours to unite the images of living nature with the grand conceptions of ideal beauty. Overlooking the productions of classic times, in which this union is so happily accomplished, because to his vigorous rather than refined perceptions its simplicity appeared poverty, he struck fearlessly into a line of art—where art alone was to be admired—where all was to be new—vehement—wonderful.

Even the manual processes necessary to realize these conceptions were to participate in the ardent temperament of the mind, by which they could have been inspired. This, indeed, forms one of the most powerful spells in the sculpture of this great artist, that between the animated forms, the breathing spirit of his composition, and the rapid, the impatient execution, there exists the most perfect harmony. The hand seems indignant at the very hardness of the marble that gives to its creations their immortality. Yet even in this respect we discover many technical peculiarities and imperfections. From having merely sketched, or at most modelled the subject in small; nay, in some instances, with no other suggestion or guide save the accidental shape of the block, he struck into the marble. While the mind, the eye, the hand, were thus in instant exertion; while propriety of expression and beauty of outline, mechanical detail and general effect were at once to be studied, error could hardly be avoided. Hence the want of proportion so conspicuous in his works,—hence so few finished, and those commonly presenting one sole point of view. As regards more individual details, in the salient lines of the contours, the circles have rarely their proper value, and the surfaces want their just fulness. Partly to compensate this deficiency in the advancing curves, partly as a characteristic distinction, which consists in strongly pronouncing the muscles, the retiring lines or muscular depressions are marked with exaggerated depth. Trusting to mechanical dexterity also, and to profound anatomical science, Buonaroti was often seduced to work from memory without reference to the living model. This frequently produces a rigidity, a want of feeling even in his best performances, paving the way for the introduction of those conventional modes which finally superseded the diligent study of nature, leading to the abandonment of every genuine principle of soft, gracious, or correct design.

No artist has ever exerted a more extensive influence, or more deeply impressed his own peculiar spirit upon art. But this influence has not been favourable to its progressive improvement, or even stationary excellence. The imitation of a natural and simple style, either in literature or the arts, will never prove injurious. But even the excellencies which this recognised, urged as the character required to the extremity of daring, necessarily became sources of error to imitators. A style of art which thus carried imagination to the very verge of possibility, which not only aspired to an excellence altogether distinct from imitation of reality, but introduced a necessity of constantly pursuing novelty; which created a standard of beauty highly artificial, and in many respects independent of nature, operated with baneful influence on the future advancement and purity of art. The works of Michael Angelo, exhibiting the principles and full development of this style, were regarded as the only models of imitation. Originality thus began quickly to disappear. The deviations even of his immediate successors from the simple and the beautiful were great, because in adopting a standard thus exclusively ideal, they receded more and more from nature.

The irregularities and defects also growing out of this system his genius alone had been able to consecrate or conceal. Deterioration thus becomes rapidly apparent in the works of inferior imitators who failed to acquire those nobler qualities by which the errors or extravagancies of mightier spirits are redeemed. From these causes, various in their effects, yet all originating in the system and style of art now explained, a decline had visibly taken place, and exaggeration, and mannerism, had evidently commenced at the close of the sixteenth century, when the principles of Michael Angelo were established in all the schools of Europe.

SECTION III.

The decline which is perceived to take place in the productions of sculpture, even from the commencement of the seventeenth century, is to be ascribed in part to causes political and moral, though more especially to those which originated in the state of art itself. Indeed, without the operation of such external influences, when a high degree of excellence has been attained in any intellectual pursuit, internal corruption never can occasion a sudden or rapid retrogression; at the same time a lapse under such circumstances always indicates an inferiority in knowledge or practice. The different states of Italy, in which the arts had been cultivated from political motives chiefly, were no longer alive to the same interests. Rome at no period had possessed a native school, cherishing the arts only as sources of political importance. Florence no longer enjoyed her free constitution; and the other states had, with the dignity, lost the sentiments of independent communities. In Bologna, indeed, a new era in painting commenced; but its principles were not calculated to bring back simplicity and correctness. In fact, the subsequent ascendency acquired by the school of the Carracci, may be numbered among the means contributing to the decline of sculpture. Moral causes also operated strongly in directing attention to other studies, and in forming intellectual habits opposed to those of the artist. A spirit of philosophical inquiry had gone abroad in the age, turning the genius of the time to mathematics and to science. Michael Angelo died at Rome on the day which gave birth to Galileo at Florence. Nature, as if unwilling to bless the same epoch with transcendant powers in opposite provinces, seemed to rob the arts in order to enrich philosophy. Poetry and the Fine Arts depend upon the same intellectual temperament, and the same state of society seems congenial to both. Hence they have generally flourished or fallen together. But between the spirit of analytical inquiry—of minute discovery which belongs to scientific investigations, and the creative fancy which leads to successful exercise of the poet's and the sculptor's art, the dissimilarity is so great that the human mind has never attained eminence in both at one period and among the same people.

The commencement of the seventeenth century thus promised by no means auspiciously for the future progress of sculpture. A crowd of undistinguished names followed the dissolution of the great Tuscan school; and when an artist of high talent at length appeared, the circumstance proved only the more hurtful from throwing splendour around a capricious and injudicious style. Bernini, born at Naples in 1598, was endowed by nature with all the qualities requisite for becoming one of the greatest of modern sculptors. No artist ever displayed happier dispositions for excelling, nor at an earlier age. Unfortunately, however, he aspired to invention instead of imitation, and chose rather to be a founder of a sect than to take his place among the fathers and chiefs of regular art.

To Bernini the beautiful simplicity of ancient taste appeared meagre in outline, poor in composition, and in effect feeble. The style of Michael Angelo he preferred as being more forcible in its impressions, but possessing a character too severe and forbidding. He aimed at eliciting a third style with distinctive qualities of its own, which should display greater strength and energy than the former, while it surpassed the latter in suavity and grace. In pursuit of these imaginary and incompatible excellencies, he deviated still further from the simple, the true, and the natural. To produce effect was now the only object of study; every means of startling attitude, voluminous drapery, forced expression, was employed to strike, to dazzle, to surprise. Statues were composed and draped after the fashion of painting; and the full-flowing robes of the Bolognese school, the most improper for the sculptor, were selected as the model which he was to follow. Thus, amid greater errors engrafted upon those of the antecedent age, Bernini, by the introduction of a style rendering less necessary the science hitherto constituting a redeeming quality in the school of Michael Angelo, and which had tended to maintain an intercourse with this primal source, prepared a more fatal separation from nature. The powers of a fine and facile execution, possessed by him in so eminent a degree, recommended or concealed the impurities of his composition, tending only to render his example the more pernicious. This style was adopted quickly and almost universally, both as it was the reigning mode, and as its author, till his death in 1680, enjoyed such dominating influence and exclusive patronage as rendered him the tyrant of art, to whom all who expected to rise in their profession or in fame, were expected to do homage. The works of Bernini in sculpture are very numerous, but all composed in the same pretending and affected style. The group of Apollo and Daphne, executed in his eighteenth year, is his most chaste performance. As an architect, the circular colonnade of St. Peter's does him more honour than his sculptures.

The most celebrated contemporaries were Algardi and Fiammingo, who, among the crowd of imitators, retained the dignity of independent, and the praise in some degree of original, minds. By the former is the largest relievo extant, representing the invading army of Attila, met in its march to Rome by St. Leo. Francis du Quesnoy, born at Brussels, thence better known by his partial surname Fiammingo, is justly celebrated as the sculptor of children. The concert of cherubs at Naples, and the two infants in a monument at Rome, are his most admired works: of which latter, Rubens, no mean judge, writes thus: "Nature rather than art appears to have sculptured them, and the marble is softened into life." But the comparative purity in the style of these two masters availed little in opposition to the influence of the reigning taste. To Bernini, but immeasurably beneath him, Rusconi succeeded as the great man of the age, the former part of the eighteenth century. The greatest work of this artist, executed with the assistance of Monnot, le Gros, Maraldi, Moratti, Ottoni, and Rossi, pupils of the last school, and deeply embued with its erroneous principles, was the colossal statuary on St. John Lateran. With this school terminated in utter helplessness the further progress of sculpture during this era. To the conclusion of the last century, indeed, a crowd of artisans continued to haunt the scenes of former glory, but their names or performances would furnish neither illustration nor pleasure.

The history of transalpine sculpture during the preceding two centuries, now demands our attention. In France the immediate pupils of Giovanni di Bologna, among whom as chief may be mentioned Adrian, Anzirevelle, Della Bella, and Tacca, fill up the interval of forty years to the commencement of the reign of Louis XIV. a period highly favourable to French sculpture, in the practice of the art at least. This patronage indeed formed a part of that national and personal aggrandisement which constituted the political rule of this reign. For the formation of a school of French art, he established academies, endowed professorships, proclaimed rewards, instituted honours, and accomplished the object. But even during this the golden age of her intellectual labours, France derived her arts from Italy; and unfortunately they were not the models of a purer age, the monuments of more manly taste that engaged imitation. The works of Bernini and of his followers, the principles of their design and composition, formed the guides of the French school. In both countries also, similarity of circumstances concurred to introduce the same vitiated style of practice and of criticism.

Of the school of sculpture in France during the reign of Louis XIV. two artists claim to be head. Gerardon, born at Troyes in 1630, and Puget at Marseilles in 1622. The style of the former, though cold and somewhat heavy in design, is noble; more correct, firm, and manly, than that of his contemporaries. He excelled in modelling, which greatly contributed to the perfection of his works, the most remarkable of which are the tomb of Richelieu, and the equestrian statue of Louis, both in Paris. His most celebrated pupils were Fremin, Charpentier, Granier, Nourisson. Were the works of Gerardon possessed of more character, and did they less frequently remind us of the productions of former masters, not many names in the history of modern art could be preferred. Strongly opposed to the disposition of his compatriot appears the character of the fiery and energetic Puget, the favourite of native writers, who are fond of representing him as the Michael Angelo of France. In execution, his style is bold, rapid, and full of movement, but in composition he is studied, in science inaccurate, and in the intellectual beauties of art, in elevation, nobleness, and grace, as also in the choice of forms, defective. The most esteemed work of this artist is the statue of Milo at Versailles, which indeed exhibits both the beauties and defects of his genius.

To the schools of these two may be referred, at least in principle, the succeeding artists of France; the manner of Puget, however, was the more popular, and becomes in some measure characteristic of the national art. Contemporaries of the above were Sarrazin and Guillain; both of considerable merit, and of fine taste, especially the former, as may be seen from the Caryatides of the Louvre. As we advance to the conclusion of the seventeenth, and especially in the early portion of the last century, French sculptors become very numerous. Among the artists who flourished during this interval may be mentioned, Le Pautre, Desjardins, Coysevaux, Vaucleve, and the two Coustou's, of whom Gregoire is highly distinguished by the horses in the champs Elysées; Falconet, celebrated for his writings and the equestrian statue of Peter of Russia at St. Petersburgh. During this period, as the opportunities of exercising it were on a grander scale, the art appeared to be in more flourishing condition than in Italy; taste in both countries, however, was alike fallen. With Louis terminated the grandeur of French sculpture; under his imbecile successor it suffered a rapid decline: yet Bouchardon, the sculptor of greatest merit under this latter reign, possessed no mean talents, as may be seen from the bronze equestrian statue of Louis XIV. of which the horse is a master-piece. Louis XVI. early evinced a disposition to patronise the fine arts, and, previous to the revolutionary excesses, had given directions for a series of statues of the great men of France. To this series may be considered as belonging the statue of Voltaire by Pigal, now in the library of the Institute. This figure, without drapery, and, as the living original was remarkable for meagreness of person, copied from a model the most emaciated and squalid to be found, gave occasion to the following epigram:

> Pigal au naturel represente Voltaire,
> Le squelette à la fois offre L'homme et L'auteur,
> L'œil qui le voit, sans parure etrangere
> Est effrayé de sa maigreur.

Pigal's finest work is a statue of Mercury, which we believe is at Lyons, of which he was a native; he founded a numerous school, of which are Mouchy, Lebrune, Moette, Bocquet, Chaudet, and others, who bring down art to our own times.

In Spain, during the preceding period, many sculptors might be mentioned; but their influence extended not beyond their own country, their works being little known without the walls of Madrid, Grenada, Cordova, Seville, where they form chiefly the internal decorations of churches. The principles of the Spanish school are derived from Italy. In Germany, the reputation of Rauchmuller of Vienna, of Leigebe in Silesia, of Schluter at Berlin, Millich, Barthel, and others maintained reputation during the period now spoken of. Ohnmacht, Sonnenschein, Nahl bring the art to contemporaries of the present century.

On reviewing what has been said, it will appear that in the fifteenth century, the fine arts became important as national causes: till this date they had flourished in connection with those of utility, rather than from abstract feeling of the pleasures awakened, or the moral impressions enforced by the great and the elegant. While sculpture in particular was thus cultivated with the ardour inspired by a fresh object, it was improved by the vigorous efforts of unworn and unshackled intellect. Hence it has been the singular fate of the sculptors of this period, to have created models in those that followed, while they have continued models themselves; to have remained originals, in succeeding ages of originality. During the sixteenth century, political causes, more remotely connected with real patriotism, an ostentatious desire of splendour, not an unaffected love of refinement, operated in the promotion of the arts; and the artificial excitement seems to have imparted a portion of its spirit to its effects. Sculpture, indeed, was practised with the magnificence and success, which power, riches, and talents, will assuredly command; but purity and simplicity of design disappeared in proportion as peculiar ideas of grandeur and novelty were pursued. Genius hovered on the very confines of credibility; its creations derived their elements exclusively from an imagination awful and imposing; but the sympathies of human feeling were overwhelmed, not awakened, by those visionary forms of gloomy sublimity and power. Art was raised to regions where nature was unknown, and where the very highest exertions of intellect and fancy could hardly maintain empire or preserve interest. It fell therefore with him who had placed it on this dangerous height. While every preceding deviation from nature and simplicity was exaggerated in the sculpture of the two following centuries, the grandeur and originality which had redeemed minor imperfections were lost in the feeble hands of imitators. Nature was everywhere abandoned, conceit and affectation usurped the names of taste and of grace; and the solitary quality which finally remained—dexterity of hand, was calculated only to increase absurdity and mannerism, by affording facility of execution to every capricious novelty.

From the age of Michael Angelo inclusive, we find that the desire of novelty, a continued endeavour to extend the boundaries of the art by the introduction of imaginary perfections inconsistent with its real character and excellence, were the rocks on which was made fatal shipwreck of truth, of simplicity, and beauty. These imagined improvements were directed to the acquisition of two grand objects. A style of composition was aimed at more purely ideal, less connected with nature than is to be found in the remains of the ancient, or in the works of the early modern masters, or than is consistent with the principles of art. As characteristics of this imaginative style, the proportions are enlarged, the expressions forced, and power and energy are given destructive of grace and of reality. This was more especially the style of the Tuscan school. In the second place, sculpture was sought to be assimilated to painting, and merit was estimated by the extent to which imitation in this respect was carried—in difficulty and variety of effect, and in complicated detail, and in volume of drapery, and latterly even in facility of production. This taste necessarily cherished the mechanical powers of execution, in preference to the unobtrusive beauties of purity and correctness of design. This style began decidedly to display itself in the school of Bernini; and subsequently sculptors excelled, or rather were less inferior, according to the manner of the painter whom they followed as a model; till finally imitating Pietro da Cortona, and even Carlo Marratti, they rendered statues confused masses of cumbrous drapery, from which heads and extremities protruded often with little apparent connection. Still the chisel was wielded in a bold and even skilful manner; but moral beauty, sentiment, and truth,—chaste design and graceful composition had long ceased to animate the proofs of its mastery.

SECTION IV.

To correct, or perhaps to avoid the corruptions of taste and false principle, is in all cases more arduous than to elevate to higher excellence a rising art. In addition to this general difficulty, two peculiar obstacles opposed the renovation of Sculpture. The aberrations first to be repressed were exactly those which appeared to indicate genius and spirit. Exterior qualities, by which alone the many judge, were in no respect deficient; indeed, an exuberance of executive dexterity and management existed, first to be reduced, consequently the preliminary steps to reformation would seem to imply diminished freedom and energy. In the second place, the fine arts generally, and our subject in particular, had suffered from a system of criticism, originated in France under Louis XIV. which had long vitiated the public mind, and misled the judgment of the artist by false refinement and conventional principle. Towards the end of last century, however, more perfect discoveries of classic remains, aided by the writings of a few enlightened authors, had begun to excite a movement towards a happier order of things. To sculpture, the influence had not extended; this art was in the hands of those who, educated in former abuses, wanted the patience and the discrimination either to perceive the evil, or to apply the favourable occurrences of the time. Reformation in art has never been accomplished by mere imitation of examples, however excellent; nor by only adopting rules in opposition to methods less pure. Some mind of uncommon firmness and good sense is required, who, beginning the art with nature, brings to the work of reformation all the original powers, with more of severe judgment than have distinguished the greater proportion of even the fathers of invention. Such a mind had not yet assumed its enlightening career. At Rome, then the only school, if school it might be named, hardly any work save a copy was attempted; or if by chance an artist aspired to an original composition, a performance was exhibited, made up of plagiarisms from ancients and moderns, combined in an union of extravagance and conceit. Such were the labours of Penna, of Pacilli, of Lebrun, of Pacetti, of Rhigi, of Angellini; and without promise of rising merit, the art seemed fast verging to extinction.

Such was the condition of Sculpture, when, in 1787, was exposed to view at Rome a work declared at once by the intelligent, "of all the monuments of modern times to approach nearest to the beauty of ancient taste." This was the tomb of Clement XIV. the celebrated Ganganelli, a work ranking among those memorable productions which mark the commencement, while they announce the continuance of a new and better era. Standing itself nobly conspicuous, it is but one step from barbarism, yet directs the eye to a lengthened prospect of renovated grandeur and beauty; the first fruits of one of those rare minds just described, more rare than even original genius, whose fire, tempered with steady judgment and patient correctness, shows them born to redeem and to elevate a fallen age. The Sculptor was Antonio Canova.

The education of this artist, self-conducted and amid difficulty of every kind, completed with successful perseverance, alone supplies ample proof of transcendant talent, and of those qualities we have pointed out as necessary in one who aspires to reform a degraded art. Fallen upon evil days, descended of obscure parentage, remote from all means of advice or instruction, he raised himself to the highest honours, and greatest of all, became the true restorer of prostrate taste. Canova was born, in 1757, at Possagno, a distant and till then unknown hamlet of the territory of Treviso. Here he was intended by his friends for the humble situation, hereditary for two generations in his family, of stone-cutter to the village. A happier destiny however awaited him. Having early discovered marks of docility and talent, he was permitted, through the benevolent recommendation of the proprietor, to attend upon a Venetian artist, then employed on some stone ornaments at a neighbouring villa. In his fifteenth year, repairing to Venice, partly aided by the same patron, and having procured a workshop in the cloisters of a convent, he struggled forward; prudence and industry preserved independence, and merit at length procured friends whom virtue ever afterwards retained. At Rome, whither he had ventured to proceed, his only certain means of support being a small pension granted for three years by the Venetian senate, he greatly recommended himself to the discerning few, by the classic elegance and purity of his first production—the group of Theseus and the Minotaur. On this account he was selected to execute the monument already noticed.

The works of Canova are too numerous to admit here of particular description, or of minute examination. The impression is yet fresh upon the memory, when representations of them arranged in his funeral hall might well have been deemed the labours of successive periods, and of a race of sculptors, not the productions of one short life—the creations of a single mind. Neither have we forgotten, while now writing on the subject, that the undertaking has been gone into, only because we have seen and examined on the spot each of these exquisite masterpieces, and that to enjoy this advantage a very considerable portion of Europe must be traversed. These works, thus in number so imposing, and so widely extending the influence of their individual excellence, may be classed as follows:

I. Heroic compositions, or subjects of masculine strength and character.

II. Compositions in which softness and grace predominate as distinctive attributes.

III. Monumental erections and sculptures.

IV. Relievos chiefly in model.

In the first of these departments only has the superiority of Canova been questioned; or rather, while his claims have been universally recognised in productions of softer grace and loveliness, his powers seem less generally appreciated in the sublimities of severe and masculine composition. He has been admitted a master of the beautiful—hardly of the grand; the Praxiteles—not the Phidias of modern art. This opinion, causes merely extrinsic and unconnected with the genius or labours of the artist concurred to originate and to maintain. Notwithstanding an early predilection for this especial branch of his profession, as appears from his own letters, and from the choice of subject, where that choice was left free, more than forty years, and those the best of life, had passed away, before a proper opportunity occurred of gratifying this inclination or of proving his capabilities. Thus his fame was first established as the sculptor of the softer affections and more tender forms of nature. The world is parsimonious of praise, nor is it easy to pass those limits which public opinion has set to its own suffrage. Subjects of gentler character seem also to be more generally pleasing in Sculpture; hence while his works in this class have been spread widely by numerous repetitions, his labours in the more elevated style have remained in the originals. But it may be justly doubted how far Canova is not even superior to himself in the grander attributes and higher walks of art. By not one, but many, groups and single statues, he has attained, in nobility of form, correctness of science, strength of character, harmonious design, and, where demanded, forceful expression some of the best effects and loftiest aims of Sculpture. Nor is this merely a general character; individual works may be instanced, in each of which, while the intrinsic requisites of excellence are conspicuous, some especial constituent of greatness is remarkable. In manly and vigorous beauty of form, where grace and elegance are justly distinguished from the effeminate, we have the Perseus; not unworthy of its immediate prototype, the Apollo. In strength, in forceful expression, and perfection of science, there is the group of the Pugilists, in its peculiar range the most classic work of modern times. In harmonious and noble composition, united with grandeur of action, the Theseus combating the Centaur, offers an admirable example; nor does the whole extent of three preceding centuries afford a happier combination of poetic feeling and natural effect. For the terrible in expression and suffering, the Hercules and Lycas carries sculpture to its utmost limits in the representation of passion, yet without extravagance. These, with the Palamedes, the Hector and the Ajax, the Paris, and others that might be added, all belong to the grand style of art, furnishing a series of works in only one of several departments unparalleled in the history of any single man; while in the beauties of sustained effect—of learned design—of boldness and exquisite delicacy of execution, they may challenge comparison with the style of any former age. On leaving the regions of poetry and fable, to whose heroic imaginings he has thus given high embodiment, we find that in the faithful portraiture of the great or the venerable realities of human life, Canova has proved himself an equal master. The statue of Napoleon is a most majestic figure, combining the ideal in composition with individual and striking resemblance. Of dignity inspiring veneration, the kneeling figure of Pius VI. which received the very last touches of the artist;—of sedate energy and classical arrangement, that of Washington, furnish fine examples. In modern art, what more worthy of the highest praise than the characteristic firmness of good intention which respires in the statue of Ganganelli? or than the solemn and affecting feebleness of Rezzonico, which speak their sole support to be in religion?

In the second division of his works, Canova remains not only unequalled but unrivalled in our days. His compositions have enriched modern art with the most glowing conceptions of elegance and grace—raised and yet more refined by the expression of some elevating or endearing sentiment.

> —— Spargi intorno sì onesta dolcezza
> Che inanzi a te non ha chi pensi vile.

In all the elements of the beautiful—in form, attitude and expression, Canova is generally—often preeminently, happy. His forms, if not always possessing the highest ideal elevation, are never mean nor common; they are ever graceful selections from nature rendered with every beautiful aid of art. Contours simple and continuous, yet varied and flowing, are sustained by profound anatomical science, still without harshness or severity. His female figures are thus equally removed from the flimsy affectations of his immediate predecessors, as from the too robust and austere proportions of the Tuscan school. It is in those compositions which admit of a direct comparison with the antique, where we sometimes remark most decidedly a deviation into the meagre and the cold, when dignity is to be united with sweetness in the female form: a defect arising from a want of harmony between the just height and fulness of the figures. Of this the Venus exhibits a remarkable instance, where we look in vain for that sustained maturity of beauty which charms in her Grecian rival, for those inexpressibly soft, yet firm and full outlines, meeting but eluding the eye, rounded into life, and lost in the animated marble. In regard to expression in the department of the graceful, the idea of Canova appears to have been to unite the two elements of sculptural design, keeping each in due subordination to the other; hence his female statues have more of expression than the antique, and less than those of the modern schools. But in this expression, though he is always true, he is not often simple, except where nothing beyond mere placidity is attempted:—effort is not unfrequently too discernible, the expression is too elaborately pleasing to please, and though we acknowledge the presence of much suavity, there is little of feeling. The attainment of that ineffable charm, grace, in all its various constituents of attitude—composition—character—arrangement—appears to have been the leading object of Canova's study, and of which he has proved himself a perfect master. In every part of each of his numerous works, even to the smallest ornament, all is the emanation of the same refined taste and cultivated mind. Indeed he has been charged with running into the extreme of affecting studied elegance—of a laboured and fastidious refinement. And without doubt, his graces would be too ornate, were not the whole effect productive of the most inimitable ease;—ease proceeding from the very perfection of labour. The attitudes have all the freedom and truth of nature—yet they are not in reality the positions which nature would readily suggest or assume, but which graceful art would select as the most uncommon or the most attractive. The choice has finally, but not obviously been determined, after much thought and many trials. Even to the minutest fold of drapery the same principle extends; all is the perfection of art, not the simple imitation of nature, but it is art by which art itself is best concealed, and which to its creations lends the enchantment of nature's own sweetest graces.

In the third division of his works Canova displays all the peculiar excellencies of his genius, with more of originality and simplicity than is perhaps to be found in his other labours. This class may be divided into two; architectural elevations supporting colossal statues—and simple tablets in relievo with sculptures the size of life. Of the former, the tombs of the popes at Rome, of Alfieri at Florence, and of the archduchess Maria Christina at Vienna, are magnificent examples, and may be compared in magnitude, as in excellence, with any similar works of modern art. The monument of Ganganelli has already been noticed as announcing the dawn of reviving purity; that of Rezzonico Clement XIII. followed and confirmed the glories of the coming day. From these the monument of the archduchess is of a character totally different, and indeed stands alone in the annals of sculpture. A simple pyramid represents the sepulchre; towards the dark and open entrance, a procession of eight figures with funereal emblems, and bearing to its last earthly resting place the urn of the deceased, appears to move with silent and stealthy pace. Here reign a simplicity and pathos which speak directly to the heart; and if we may judge from the impression made upon our own feelings, no record of mortality ever better accomplished its purpose,—whether to awaken regret for departed virtue—or to tell by its own perfection—that there exists an intelligence in man which shall live beyond the grave.

The monumental relievos constitute a numerous and very beautiful class of works, and though composed of nearly the same slender elements of design, a female form mourning over a bust or an urn, yet they exhibit much diversity of character and arrangement, with great excellence of execution. With one exception they are all bassi relievi, extremely classical in design, and may be said to have been invented by Canova, since we trace resemblance only on one remain of Grecian sculpture. In many cases, however, greater force might have been given, if the contours, instead of melting gradually into the plane of the tablet, had been terminated by a perpendicular outline, as in several of the most admired specimens of antiquity. A firmer and more vigorous effect would thus have relieved the whole piece, which often resembles a highly finished picture, where the light is too equally diffused without just equivalent of shadow. To this the grand relievo on the monument of the Countessa de O'Hara offers a most splendid exception.

Not, however, till 1790, as a relaxation from severer labours, did Canova turn his studies to relievos properly so called, nor, except in one or two instances, did he execute any example in marble. But in this beautiful department of the art, he modelled numerous subjects from history, poetry, and mythology, all displaying the same pure taste and severely regular judgment as appear in more finished works. But, devoting his powers to more arduous pursuits, he left open this career for the exertions of others.

There still remains to be explained one distinctive characteristic of the works before us; namely, the uniform and exquisite beauty of the execution. They unite the dexterity and vigour of handling, which formed the praise of Michael Angelo and Bernini, with a delicacy, elegance, and truth, altogether and exclusively their own. Canova appears to have been the first to remark, certainly the earliest to imitate, this excellence in the models of antiquity, an excellence of the very highest import, not so of itself, but because it can be rendered pleasing only when united with intrinsic beauty of composition and veracity of science. A statue deficient in the higher qualities of art, would by nice finish be rendered only the more ungraceful. In sculpture, works of the greatest merit alone admit with advantage the external embellishment of the surface. The most perfect statues of antiquity are also the most highly wrought. But modern artists either studied general effect to the disregard of beautiful finish; or in the endeavour to attain minute excellence, fell into the dry and the laboured. For Canova it seemed to be reserved to combine grandeur and breadth of effect with the most delicate touch and the most careful detail. To him modern practice is indebted for this most valuable precept, elicited from a comparison of the antique with nature; namely, that from whatever resources the figure may be composed and brought nearly to a termination, the last touches, the final surface, must be faithfully copied from individual nature. This principle has in every instance guided his hand in the mechanical details. Another may be distinguished which has uniformly traced the gracious and sweetly flowing outlines of his statues; namely, the ternary combination of members in a whole—or that law of arrangement, which in the living as in the inanimate world, seems to create beauty by the relation of a primary and two secondary forms. To the former of these laws is to be ascribed the yielding and elastic, the almost living surfaces of Canova's statues; to the latter, their delightful propriety and just ordonnance of parts, yet devoid of all obvious symmetrical or artificial balancing of masses or attitudes. The exquisite purity of surface and lubricity of contour thus produced, gave rise to the supposition, that less legitimate operations of secret washes or preparations were employed. But though he certainly did make experiments on this subject with a view of discovering the processes with which there is reason to believe the Greek artists were acquainted; yet over his own works was merely poured a solution of pumice stone, or emery in water, in order to equalize the effects of light, and to take off the glare of recent finish. In the construction of the clay and stucco models, the *crete* and the *gessi* of the Italian sculptors, Canova likewise introduced the most important improvements; being the first who employed models fully and carefully completed, and the exact size of the intended marble, even in cases of colossal proportions. By this means the labour of the sculptor has been incredibly abridged, and his valuable time saved; for thus the formation of the statue to a very high degree of forwardness may be safely committed to the mere labourer. In short, not one branch of his profession was left by Canova unexercised nor unimproved.

The preceding series of his works, which, including busts and portraits, amounts to upwards of two hundred, fully establishes this, as these works exhibit the same merit in every department of the art, and in each separately, attaining a degree of eminence alone sufficient to insure immortality to any single artist. In this view there can be no hesitation in pronouncing Canova the most indefatigable; nor, when we consider the influence of these labours, and of the principles which they illustrate and enforce, the greatest of modern sculptors. Yet in estimating truly the rank and constituents of his genius, there arises no small difficulty. The very fecundity of that mind diffusing its richness over every province of the art, and in each varied character constantly displaying by the same admirable judgment and fine taste, increases this difficulty by blending into one harmonious whole the marked qualities and outbreakings of peculiar energies usually indicative of lofty powers. Hence we might be inclined to pronounce his genius distinguished more by correctness than by fire. Yet though such really seems externally to be the character impressed upon their exercises, of his powers generally, the estimate would be erroneous. His genius wanted neither fire nor enthusiasm—his imagination was uncommonly active, and stored with materials; but over the treasures thus lavishly poured forth, judgment and taste presided in severe scrutiny. Hence, though in composition rapid and energetic, in correcting and finally determining, he was slow or even fastidious; often changing, but always improving. With Dante he could truly have said

L' ingegno affreno
Perche non corra che virtù nol guidi.—
Piu non mi lascia gire il fren' dell'arte.

Such an intellectual organization is by no means favourable to that grandeur, usually associated with our ideas of the highest genius, which hurries alike the artist and the spectator beyond the bounds of reality; which, deriving its very mastery from daring disregard of rule, grasps with dangerous hardihood those aspiring graces, pardoned only when successful, and even then, however they may elevate the individual, not enriching art with useful examples or solid acquisitions. But such a mind was eminently fitted for exalting fallen taste, especially for succeeding in the serene majesty and regular magnificence which constitute the true greatness of sculpture. Hence in the labours of Canova there is to be found this superiority, that his march is uniformly dignified and consistent; correct without coldness, if he rarely attain the height of sublimity, he never falls beneath himself or into the extravagant in the pursuit. Compared with the ancients, he remains inferior, in as far as he has, like every modern, been indebted to the precepts and the examples of Greece. But his was no servile imitation, to have studied constantly their works, to have discovered and applied their principles, forms his greatest praise, and constitutes one of the most essential services ever rendered to sculpture. Among the moderns, Canova claims pre-eminence as being the first to establish the grounds of progressive improvement on genuine and universal principles of art. The greatest names whose labours illustrate former ages, either wrought without principles—their skill was merely personal, and the same tomb thus closed over the knowledge and the possessor; or they were at best but founders of partial theories, and of exclusive schools. By the sculptors living prior to the sixteenth century, accuracy of imitation was the only essential generally known and practised. The masters of that splendid era combined, with forceful execution, the magnificence of elevated—but of peculiar theory. Before Canova, no one had exhibited in his own works a just harmony between the several requisites of excellence, nor had given in practice rules conducting to general and undeviating results. From a degraded and lost condition he not only elevated art to a state of perfection, such as may be compared with its brightest periods, but founded this improvement on principles that lead progressively to greater excellence, or at least cannot bear to error since they conduct to nature. It is this remounting to the eternal sources of truth and beauty, this influence of universal principle, this exhibition of unchangeable and uniform art, which will render the works of Canova a standard in all ages to come—inseparably associating his merits with the future history of sculpture.

We approach with respectful diffidence our more immediate contemporaries. A few notices of those names who already belong to posterity may, however, prove not unacceptable.

Among the Italian sculptors,—consequently among the masters of Europe, Thorwaldsen has obtained the first place since the death of his illustrious contemporary above mentioned. The life of this artist displays a striking instance of the powerful volitions and deep-toned sensibilities of genius. Thorwaldsen was born at Copenhagen in 1771-2. His father, a builder in that city, possessing some knowledge of the arts, began early to cultivate the turn displayed by young Albert for sculpture. The years of childhood were passed in modelling and in carving architectural ornaments at home; on early entering a student in the academy of fine arts, in which professors, enjoying pensions from the government, are bound to give instruction without fees, he soon became distinguished; on every occasion carrying off the prizes proposed as the rewards of industry and merit. In his seventeenth year an extraordinary gold medal happened to be offered for the best relievo on the subject of sacking the temple at Delphi. The competitors were placed in separate apartments, and thus shut up from external communication, were to finish their respective pieces, or to relinquish the contest. The latter resolution, it is said, had almost been adopted by our youthful aspirant, whose feelings were so tremblingly alive to the peculiarity of his situation, that after hours of fruitless solicitude, he had not been able even to make an attempt. At length the flow of inspiration came; Thorwaldsen produced a model, not only unanimously declared the best on the occasion, but of such pre-eminent excellence as to entitle him to the award of the great gold medal assigned to the most accomplished pupil of the Danish academy. To this honour a pension was also joined for assisting the holder in foreign travel. It was thought advisable, however, that on account of inexperience, some time should be permitted to elapse before this latter advantage should be embraced. Accordingly, for some years Thorwaldsen remained at Copenhagen, where he executed several works of great promise. When at length he set out for Italy, having landed at Naples, the most longing desire of returning to his native land seized his mind; and not without difficulty was he prevailed upon, in the first place at least, to visit Rome. The sight of this venerable capital, and the friendly offices of some of his countrymen whom he there met, seem to have in part reconciled him to absence. But a new anxiety arose, and threatened to put a stop to all future hopes. He saw and ardently appreciated the rich treasures of art contained in that city; but the perfections of past exertions, far from stimulating, overwhelmed his spirit. He despaired of ever accomplishing an effort which should deserve mention in the place where these were to be found, and deep melancholy preyed upon his mind. For more than a twelvemonth he remained in a state of depressing irresolution, during which studies were thrown entirely aside, or resumed only to increase his mental sufferings, and almost to confirm into permanent disability the temporary diffidence of high-wrought feeling. The encouragement and advice of friends, his own ardent aspirations after honest fame, conquered at length this painful sentiment. Once more he addressed himself to his art, and produced the statue of Jason, a work which warranted the most honourable expectations, although the artist was yet personally so little known, that he himself was asked by one at a large party if he knew the young Dane who had just produced the admired model of Jason. Other labours followed, and the fame of Thorwaldsen was established by the two statues of Mars and Adonis, each of very opposite but of great beauty. Among the foremost to acknowledge and to praise the merits of these performances, was Canova, the sole individual who had reason to feel alarm from the success of such a rival. Canova, in 1809, received an order from the Danish monarch for four Bassi relievi, to be placed in the cathedral of Copenhagen; this order he declined, representing the justice of employing equal ability in a subject. Nor was the conduct of Thorwaldsen less noble.

> But let not sculpture-painting-poesy,
> Nor they, the mighty masters of these spells,
> Detain us,—our first homage is to virtue.

Among the masterpieces of Thorwaldsen, executed since the full establishment of his reputation, may be enumerated, the Graces—the exquisite allegories of Night and Aurora in relievo—the statue of Mercury as a shepherd—the triumph of Alexander, a relievo, ordered by Napoleon for the vice-royal palace at Milan—and, lastly, the colossal statues of Christ and the Apostles, commissioned for his native city. From these works, a just estimate of the Danish sculptor's powers may be formed. The character of these powers is certainly of a very elevated rank, but we apprehend is not to be placed so high as has often been done. The genius of Thorwaldsen is forcible, yet its energy is derived more from the peculiarity than from the real excellence of his manner. His ideal reminds us less of antiquity or of nature than of his own mind—it is the offspring of an imagination seeking forcible impression in singular combinations, rather than in general principles, and therefore hardly fitted to exert a lasting or beneficial influence on the progress of art. His aims appear hitherto to have been chiefly directed to the attainment of simplicity and of imposing effect. That the former quality, so essential to genuine sculpture, is in many instances very successfully preserved, will not be denied; but the simple differs widely from the meagre and the rude; and in the works of the Dane, the distinction is not always observed. This especially appears in those compositions wherein grace should be the predominant feeling; these are too austere, and without due refinement of character. The forcible, too, often approaches the exaggerated, as is particularly apparent in the air and contours of the heads, which, though grand and vigorous, are rarely found to harmonize in the principles of these effects, with the majesty and regularity of general nature. In strong contrast with the powerful conception thus displayed in the heads, is the feebleness frequently conspicuous in the attitudes and forms. The first have a littleness of manner, a cramped and studied action; while the second want firmness, sustained effect, and fulness of contour. Of the beauties and defects of Thorwaldsen's style, the Mercury may be pointed out as an admirable example, and as best known, from several models in this country. The figure is seated in the act of unsheathing a sword, with which to slay Argus, whom he had just lulled to sleep by the sweet melody of a pipe still held in his hand. The general idea of the figure is beautiful, we would say poetical in no ordinary degree. The head is of exquisite beauty, the prescriptive forms of antiquity being here too obviously associated to permit wide deviation. But when we scrutinize the more particular conduct of the piece, it is far from corresponding in manly character and science with these external excellencies. The attitude is too studiously contrasted—too artificially balanced; while, with a prettiness of action utterly unequal to the effort, he is attempting to draw a ponderous falchion, by slightly pressing the scabbard between his heel and the trunk against which he leans. The forms likewise are poor and feeble, without vigorous rendering, and destitute of their full roundness of outline. This last is the leading defect in the modelling of Thorwaldsen, which probably has arisen from his greater practice in relief. It is in this latter department that his genius is most unexceptionably to be admired. The frize representing the triumphal entrance into Babylon, notwithstanding an occasional poverty of invention, is one of the grandest compositions in the world; while nothing can exceed the delicacy of execution, and poetic feeling, in the composition of the Night, or the Aurora. But in statues, Thorwaldsen excels in those only whose lineaments and expression admit of uncontrolled imagination, and which may not be tried by regular principles or natural effect. Hence, in this department, the Apostles are by far the most excellent of his works, because the subject admitted novel or even uncommon modifications of the imagination. In short, Thorwaldsen possesses great, but singular, and in some respects erratic genius. His powers of fancy excel those of execution; his conceptions seem to loose their value and their freshness in the act of realizement. As an individual artist, he will command, and he deserves a high rank among the names that shall go down to posterity. As a sculptor, however, who will influence, or has extended the principles of his art, his pretensions are not great; or should that influence and these pretensions not be thus limited, the standard of genuine and universal excellence will be so far depreciated.

The present school of Italy has hitherto proved hardly worthy of these two great leaders. In the pursuit of certain mistaken notions of refinement, vigour and simplicity of character have been lost. The numerous imitators of Canova have omitted the study of his learned principles, and too often have followed with exaggerated effect the only failing towards which he inclines—elaborate grace. In French sculpture, as in painting, the modern school exhibits more of science than of feeling. Like Poussin, the artists of the present day seem to have so long devoted their attention to the forms of the antique, that they have forgotten living nature; but unlike their illustrious countryman, they have failed to realize the sentiment of antiquity. They have imitated faithfully the cold and correct lineaments—the canons of art: but the essence which unites art to nature—which breathes into Grecian statuary the breath of life—has escaped. In Germany, the studios of Vienna and Berlin appeared to us deserted from want of encouragement: in the younger Shadoff, who died in the prime of manhood, that country lost an artist of high promise. His *Filatrice*, or girl spinning, ranks among the most exquisite imitations of simple nature which modern times have produced.

If hitherto little has been said of British sculptors, two circumstances will explain the cause of this silence. Till the present age could boast of native artists, sculpture amongst us was an exotic—cultivated by foreigners, constituting no portion of national glory, and regarded with few or no national sympathies. Again, whatever efforts have been accomplished, these, except, in one or two instances, have produced no influence on the general progress of taste. In architecture, indeed, during the reign of Charles I. this country undoubtedly excelled every other in point of classical purity, if not in magnitude of undertaking. But the refinement was short-lived; the stern enthusiasm of the true—the coarse hypocrisy of the pretended republicans, and the turbulent spirits of all, rendered England an ungenial clime for the arts of elegance. Subsequently, Cibber, Roubilliac, Scheemacher,—all our celebrated sculptors,—were foreigners. Bacon, Banks, Jusson of the last age, were natives, and of merited celebrity; still their isolated labours tended slightly towards the formation of a school of British sculpture. By the distinguished masters of the present day this has been effected; and if we do not equal our neighbours on the Continent in the number, or probably in the separate excellence of works, yet speaking of the principles which guide the practice of our sculptors, and of the progress already made, we hesitate not to affirm, that this school has produced names equal to any in modern art; and that at this moment, in rectitude and sobriety of precept —in the walk which has hitherto been followed, where nothing is yet to be unlearned, and which must infallibly conduct to the very perfection of sculpture, the British school is the first in Europe. To particularize individual names might seem invidious, and would certainly prove an ungrateful task; but Flaxman we have unhappily lost; he too surely belongs to posterity; and Chantrey confessedly stands at the head in the province he has selected. In the sculpture of portraits, we have already spoken of the artists of Augustus' reign, and we know not if, since that period, any has ever so nearly approached the last lingering excellence of Greece as Chantrey. Indeed, the general effect of his busts and portraits, as regards their admirable representation of character, "La scultura del cuore," as it has been expressed, the works of the English artist are not unlike, and not inferior to those mentioned of that period.

Flaxman has more widely extended the influence of his genius—more intimately connected his labours with general improvement, than any other English sculptor. Towards the propitious revolution which has been described as taking place about the conclusion of last century he contributed; and had he then continued to remain in Italy, would have divided honours not unequally with the great reformer of taste. As it is, the artists and intelligent critics of that country admit his claims, regretting only their want of due acquaintance with his works. One of the most judicious of Italian writers thus speaks of Flaxman: "Gli debbe moltissimo, poi che quanto di lui cognosce servi grandamente a svegliare da una certa letargia monotona, e far risurgere il gusto dello stile aureo, e severo dell' antichità ch' egli seppe applicare alle sue invenzione." Even in early youth, Flaxman was distinguished from the crowd, by devotion to the study of the antique, and by fearless but judicious disregard of those feeble and conventional modes by which art was then disgraced. He was among the first, if not the earliest, to awaken the long dormant energies of sculpture—to unite art anew with nature, and with its own best examples. The simple, the grand, and the severe of the ancient remains he made his own; nor is there one name among all those now enumerated, who in these attributes has excelled the best works of our countryman. Since the ages of Grecian genius, we no where find greater meaning—more deep feeling of truth, with less pomp of art, than in the sculpture of Flaxman. Excelling both Canova and Thorwaldsen in the inventive powers of the mind—in all that constitutes the epic of art—he is inferior in the grace and facility of execution. Had his mechanical capabilities in modelling and in finishing equalled the loftiness of his conceptions and the purity of his taste, no sculptor of modern times would have enjoyed higher fame than Flaxman.

We omit with regret, yet not unadmired, not a few names of living English sculptors. In favour of these, however, we again repeat, that, looking prospectively—founding our remarks as much on what may be—as on what has been, no school in Europe can at this moment boast of happier auspices, of more vigorous practice, or of sounder principle. The noble and manly character of sculpture agrees with our national genius, harmonizes with our free institutions, and finds in our history sources of brightest inspiration. But to realize these advantages, let our style, especially here, be truly British; we have hitherto taken too much of our principles and of our criticism in the fine arts from others. Let us in future depend on ourselves. Let the British sculptor take nature, and antiquity, of which he possesses now the most perfect examples in existence—let him take these as his sole guides—and he must excel.

SCURVY. See MEDICINE.

SCUTARI, or ISKENDERIE, a large fortified town of European Turkey in Albania, is situated on the river Bojane, at the south east extremity of the lake of Scutari, which is about 16 miles long and 7 broad. The town is divided into four quarters, and has several mosques and Greek churches. It is the see of a bishop, and the capital of a pachalic. The plain on which it stands is one of the richest in Albania, abounding in vines and olives, and adorned with numerous hamlets and country houses. Population 12,000, composed of Turks, Greeks, and Albanians. Distance from Constantinople 448 west.

SCUTARI, the Chrysopolis of the ancients, a large town of Asiatic Turkey, in the province of Natolia, beautifully situated opposite to Constantinople on the Bosphorus, on the slope of several hills, and richly intermingled with trees. The strait here resembles a large lake surrounded with large cities. This town being the rendezvous of the caravans from the interior of Asia, carries on a considerable trade. The summits of the hills above the town command the finest views of Constantinople and the adjacent country. It is a fashion among the Turks at Constantinople to be interred at Scutari. Population 30,000.

SCYLLA, now CAPE SCIGLIO, a rocky promontory at the entrance of the strait of Messina, which separates Sicily from the territory of Naples. Projecting into the sea, and stemming the waters as they flow through the narrowest part of the strait, a formidable current is produced, which, with an opposite wind, has a tendency to drive vessels on the opposite rocks of Charybdis. The smaller rocks near the base of the promontory increase the danger; and the tremendous noise of the waters dashing against the caverns, strikes terror into the inexperienced mariner. The height of the rock is about 200 feet. See MESSINA.

SCYLAX, an ancient geographer, was born at Caryanda in Coria; and according to Suidas, was the author of a Periplus of the coasts beyond the Pillars of Hercules, of a book respecting the Heraclides, a description of the Circuit of the Earth, and an Answer to Polybius's History. This Periplus, which is still extant, is a short survey of the coasts of the Mediterranean, the Euxine, and part of the west coast of Africa, as surveyed by Hanno. According to Herodotus, Scylax, along with others, was employed by Darius, son of Hystaspes, to discover the embouchure of the river Indus. "Proceeding," says Herodotus, "from the city of Caspatyrus, and the Pactyian territory, they sailed down the river in an easterly direction to the sea, and then continuing their voyage on the sea westward, they arrived on the 30th March, at the place where the king of Egypt despatched the Phœnicians to circumnavigate Lybia. After their voyage, Darius subdued the Indians, and opened the navigation of the sea." Some authors are of opinion, that the extant Periplus was not the production of the Scylax mentioned by Herodotus. It was edited by Vossius in 1639, by Gronovius 1697, and by Hudson in 1698. See the *Athenæum*, vol. iv. p. 32.

SCYTHIA is the name given in ancient times to an extensive country, extending from the 25th to the 116th degree of east longitude, and from the Circassian mountains to the Arctic circle. It was divided into Scythia in Europe and Scythia in Asia, these divisions being separated by the two Sarmatias in Circassian Turkey. See *Ancient Univers. Hist.* vol. iv.

SEBASTIAN, ST. a frontier town of Spain, in the province of Biscay. It is situated at the mouth of the little river Urumea, and between two arms of the sea, about ten miles from the mouth of the Bidassoa, which separates France from Spain. The town contains 20 streets, several of which are wide, strait, and paved with large smooth stones. There are here three churches, five convents, an hospital, and a naval academy. The town is flanked with bastions and half moons, and the citadel occupies a conical and bare eminence, ascended by a spacious path. The harbour, enclosed by two moles, holds only about 30 merchant vessels. There were here five manufactories of hides and leather, some tan-yards, and a manufactory of anchors and cables for the royal navy, when this city was taken by the British on the 31st of August, 1813, (see FRANCE and SPAIN.) It was almost entirely laid in ashes, but has since been rebuilt. Population 12,000. East longitude 1° 58′ 30″; north latitude 43° 10′ 30″.

SEBASTIAN, ST. See BRAZIL.

SECEDERS, the name given to a numerous and highly respectable body of Presbyterians who have seceded or withdrawn themselves from the Established Church of Scotland. This secession took place in August, 1733, in consequence of a decision of the General Assembly, carried by the casting vote of the moderator, by which Mr. E. Erskine of Stirling, Mr. W. Wilson of Perth, Mr. A. Moncrieff of Abernethy, and Mr. J. Fisher, minister of Kinclaven, were expelled from the Church of Scotland for the boldness with which they attempted to alter the law of patronage. The Assembly, which met in May, 1734, empowered the Synod of Perth and Stirling to receive the ejected ministers into communion with the church, and to restore them to their respective charges. This resolution, however, was accompanied with the express direction, that the synod should not take upon them to judge of the legality or formality of the former procedure of the church's judicatories in relation to the affair, or either approve or censure the same. Although this resolution was a complete triumph to the seceding clergy, yet they refused to return to the church courts on this ground; and they published their reasons for this refusal, and the conditions on which they were willing to return into the bosom of the church. Having created themselves into an ecclesiastical court, under the name of the *Associated Presbytery*, they published what they called an *Act, Declaration, and Testimony*, to the doctrine, worship, government, and discipline of the Church of Scotland. They were now joined by other four of the brethren, and the Associated Presbytery consisted of *eight* clergymen. As the congregation of these individuals had become very numerous, the General Assembly of 1738 ordered the eight ministers to be served with a libel, and to appear before the Assembly of 1739. They accordingly appeared as a constituted Presbytery, and having declined the Assembly's jurisdiction, they instantly withdrew. The Assembly of 1740 deposed them from the office of the ministry, but they erected regular meeting houses, where they exercised their clerical functions till their death.

In 1745 the Seceders had become so numerous that they formed one Synod, consisting of three different Presbyteries. In 1747, however, a controversy arose among them respecting the legality of the burgess oath, in which burgesses professed "the true religion presently professed within the realm, and authorised by the laws thereof." The presbytery, who asserted the lawfulness of the oath, were called *Burghers*, and those who condemned it *Antiburgher Seceders;* and under these names they formally separated into two distinct communions. This separation continued till within these few years, when an union took place, and the two classes of Seceders were reunited under the name of the *United Associate Synod of the Secession Church*, consisting, in 1827, of 19 presbyteries and 333 churches. About 50 congregations of the *Burgher Synod* refused to enter into the union, and now form the *Original Burgher Associate Synod;* and 16 congregations of the Antiburghers likewise refused, and form the *Constitutional Presbytery*, or *Original Antiburghers.* These different bodies have each Professors of Theology, by whom their students are instructed in theological literature.

The Relief Seceders, who separated from the Church of Scotland solely on the ground of church-patronage, now consist of 84 congregations. They have now a Professor of Divinity of their own, their students having been till lately instructed by the Professors of Theology in the Established Church. All the clergy of these different sects of Seceders are well-educated and highly respectable individuals, and are in no respects inferior to the Established clergy, either in theological or in secular learning. See our article SCOTLAND.

SECOND-SIGHT, or TAISCH in Gælic, is the name given to one of the superstitions of our countrymen in the Highlands of Scotland.

The person who possesses this extraordinary faculty is supposed to see, in his mind's eye, events which are taking place at a distance, and even those which are to take place at some remote period.

The visions which are thus presented to the eye, or to the imagination, relate to subjects of all degrees of importance, from the most trifling to the most interesting; and sometimes they are so truly ludicrous that a person who is disposed even to be credulous, cannot fail to regard them as the inventions either of weak or of wicked minds.

Disposed as we are to consider the second sight as a gross superstition, we should not have deemed it necessary to occupy our pages with any account of it, had it not had its peculiar locality in our own country. In a Scottish work, however, foreigners may expect to find some notice of a Scottish superstition, and, on this ground, we have ventured to give our readers some idea of its nature and pretensions. It appears to us that many of the facts which have been brought forward in support of the existence of a *second-sight* may be simply admitted without adopting the conclusion to which they are supposed to lead. There are few men of warm imaginations and contemplative natures, who are not in the habit of seeing in their mind's eye vivid dramatic representations, in which their relations and friends generally perform the most conspicuous parts. Without being able to trace the association, how often do we see a friend or a relation sinking beneath the wave, falling in battle, suffering under the hands of the executioner, or stretched a lifeless corpse on a bed of sickness. These pictures are often presented to us in all the freshness of reality, but frequently in the most mutilated and imperfect state. We cannot tell how the drowning man fell into the sea, in what battle the victim bleeds; for what crime our friend has suffered, or of what disease he has died. We merely see him in one or other of these distressing situations, and so singular is the ambiguity which accompanies these visions, that the person thus seen may be one of two friends; he may bear the name of one and yet have the appearance of another; he may stand to us in the relation of a parent or a child, and yet some circumstance may attend the vision which proves that he is neither. The mind, in short, of an idle, dreaming, and fanciful man, who is not engrossed by the cares and active business of life, is continually at exercise, roaming wherever it listeth, and covering its track with creations and visions of all kinds. When a friend suffers or dies, he can scarcely fail to have anticipated his agonies; when an unexpected event occurs, he must have encountered something convertible into it among his day dreams. When an enemy lands on his coasts, he is likely to have seen him in the offing during his nocturnal cruises. If our Highland seers had put on record all their visions, and given us an account of those which were not realized, as well as of those which appeared to them true, we should doubtless have been able to explain their second-sight by the ordinary doctrine of probabilities.

Although we do not think that any other explanation of second-sight is necessary than the above, yet we doubt not our readers may be gratified with the following observations on the subject by Dr. Beattie and Dr. Johnson, on the opposite sides of the question.

"The Highlands of Scotland," says Dr. Beattie, "are a picturesque but a melancholy country, having long tracts of mountainous desert covered with dark heath, and often obscured by misty weather; narrow valleys thinly inhabited, and bounded by precipices resounding with the fall of torrents; a soil so rugged, and a climate so dreary, as in many parts to admit neither the amusements of pasturage nor the labours of agriculture; the mournful dashing of waves along the friths and the lakes that intersect the country; the portentous noises which every change of the wind, and every increased diminution of the waters, is apt to raise in a lonely region full of echoes, and rocks, and caverns; the grotesque and ghastly appearance of such a landscape by the light of the moon; objects like these diffuse a gloom over the fancy, which may be compatible enough with occasional and social merriment, but cannot fail to tincture the thoughts of a native in the hour of silence and solitude. If these people, notwithstanding their reformation in religion, and more frequent intercourse with strangers, do still retain many of their old superstitions, we need not doubt but in former times they must have been much more enslaved to the horrors of imagination when beset by the bugbears of popery and paganism. Most of their superstitions are of a melancholy cast. That of second-sight, by which some are still supposed to be haunted, is considered by themselves as a misfortune, on account of the many dreadful images it is said to obtrude upon the fancy. It is said that some of the Alpine regions do likewise lay claim to a sort of second-sight. Nor is it wonderful if a lively imagination, immured in deep solitude, and surrounded with the stupendous scenery of clouds, precipices, and torrents, should dream (even when they think themselves awake) of those few striking ideas with which their lonely lives are diversified; of corpses, funeral processions, and other subjects of terror; or of marriages, and the arrival of strangers, and such like matters of more agreeable curiosity. Let it be observed also, that the ancient Highlanders of Scotland had hardly any other way of supporting themselves than by hunting, fishing, or war—professions that are continually exposed to fatal accidents. And hence, no doubt, additional horrors would often haunt their solitude, and a deeper gloom overshadow the imagination even of the hardiest native. That any of these visionaries are apt to be swayed in their declarations by sinister views we will not say; but this may be said with confidence, that none but ignorant people pretend to be gifted in this way. And in them it may be nothing more, perhaps, than short fits of sudden sleep or drowsiness, attended with lively dreams, and arising from some bodily disorder, the effect of idleness, low spirits, or a gloomy imagination. For it is admitted even by the most credulous Highlanders, that as knowledge and industry are propagated in their country, the second sight disappears in proportion; and nobody ever laid claim to the faculty who was much employed in the intercourse of social life. Nor is it at all extraordinary that one should have the appearance of being awake, and should even think one's self so, during those fits of dosing, that they should come on suddenly, and while one is engaged in some business. The same thing happens to persons much fatigued, or long kept awake, who frequently fall asleep for a moment, or for a long space, while they are standing, or walking, or riding on horseback. Add but a lively dream to this slumber, and (which is the frequent effect of disease,) take away the consciousness of having been asleep, and a superstitious man may easily mistake his dream for a waking vision; which, however, is soon forgotten when no subsequent occurrence recals it to his memory; but which, if it shall be thought to resemble any future event, exalts the poor dreamer into a Highland prophet. This conceit makes him more recluse and more melancholy than ever, and so feeds his disease, and multiplies his visions, which, if they are not dissipated by business or society, may continue to haunt him as long as he lives, and which, in their progress through the neighbourhood, receive some new tinctures of the marvellous from every mouth that promotes their circulation. As to the prophetical nature of this second-sight, it cannot be admitted at all. That the Deity should work a miracle, in order to give intimation of the frivolous things that these tales are made up of, the arrival of a stranger, the nailing of a coffin, or the colour of a suit of clothes; and that these intimations should be given for no end, and to those persons only who are idle and solitary, who speak Gaelic, or who live among mountains and deserts, is like nothing in nature or providence that we are acquainted with, and must therefore, unless it were confirmed by satisfactory proof (which is not the case), be rejected as absurd and incredible. These visions, such as they are, may reasonably enough be ascribed to a distempered fancy, and that in them, as well as in our ordinary dreams, certain appearances should, on some rare occasions, resemble certain events, is to be expected from the laws of chance; and seems to have in it nothing more marvellous or supernatural, than the parrot, who deals out his scurrilities at random, should sometimes happen to salute the passenger by his right appellation."

To these objections Dr. Johnson replies, that by presuming to determine what is fit, and what is beneficial, they presuppose more knowledge of the universal system than man has attained: and therefore depend upon principles too complicated and extensive for our comprehension; and that there can be no security on the consequence when the premises are not understood; that the second-sight is only wonderful because it is rare, for, considered in itself, it involves no more difficulty than dreams, or perhaps than the regular exercise of the cogitative faculty; that a general opinion of communicative impulses, or visionary representations, has prevailed in all ages and all nations; that particular instances have been given with such evidence, as neither Bacon nor Boyle has been able to resist; that sudden impressions, which the event has verified, have been felt by more than own or publish them; that the second sight of the Hebrides, implies only the local frequency of a power, which is nowhere totally unknown; and that when we are unable to decide by antecedent reason, we must be content to yield to the force of testimony. By pretension to second sight no profit was ever sought or gained. It is an involuntary affection, in which neither hope nor fear are known to have any part. Those who profess to feel it do not boast of it as a privilege; nor are they considered by others as advantageously distinguished. They have no temptation to feign, and their hearers have no motive to encourage the imposture."

SECTIONS, Conic. See Conic Sections.

SECTOR, called by the French the *Compass of Proportion*, is the name of a mathematical instrument in common use for determining the proportion between similar quantities.

It consists of two flat legs, or rules, made of wood, brass, or ivory, which, being moveable round a common axis or joint, represent the radii of a circle. Hence the double lines which belong to the sector can be made to fit all radiuses and all scales, whereas common single lines are suited only to one radius or scale.

The sector depends on the fourth Proposition of the VIth Book of Euclid, or the XVIIIth Proposition of Section IV. of our article Geometry, where it is demonstrated that equiangular triangles have their homologous sides proportionals. Let, for example, the lines BD, BC. (Geometry, Plate CCLXXII. Fig. 123.) represent the legs of the sector which open and shut round B as a centre, and let BA, BE be equal sections or distances from the centre of motion B: then, if the points C, D; E, A, be joined, the lines EA, CD, will be parallel, and consequently, the triangles BAE, BDC, similar; hence, BA : AE = BD : DC; and therefore, if BA be the half, third, or fourth, &c. of BD, AE, will be the half, third, or fourth, &c. of DC. Consequently, if BA be the chord, sine, or tangent, of any number of degrees to the radius BD, AE will be the same number of degrees to the radius DC.

The scales commonly engraven upon the best sectors are divided into *single* and *double*. The single scales are the same, and used in the same manner as those put upon *Gunter's* Scale, which we have fully described in our article Navigation. They have no connection with the property of the sector, but are merely put on to fill up usefully the vacant spaces which are not occupied by the *double scales*. The *double scales* consist of two similar single scales, each of which is engraved twice on the same face of the instrument, viz. one on each leg, each scale occupying a symmetrical position upon the legs.

The following table shows the nature of the scales generally put on.

Double Scales.

1.	A Line of Lines, or equal parts	marked	Lin.
2.	Chords		Cho.
3.	Sines		Sin.
4.	Tangents to 45°		Tan.
5.	Secants		Sec.
6.	Tangents to above 45°		Tan.
7.	Polygons		Pol.

Single Scales.

1.	Inches, each divided into 8ths or 10ths		
2.	Decimals containing 100 parts		
3.	Chords	marked	Cho.
4.	Sines		Sin.
5.	Tangents		Tan.
6.	Rhumbs		Rhum.
7.	Latitudes } For dialling		Lat.
8.	Hours } For dialling		Hou.
	Longitude		Lon.
	Incln. Merid.		In. Mer.
	Logarithms of Numbers		Num.
	Logarithms of Sines		Sin.
	Logarithms of Versed Sines		V. Sin.
	Logarithms of Tangents		Tan.

The single scales above-mentioned may be all used whether the sector is open or shut, but the double scales cannot be used without opening the sector.

The method of laying down the double scales by means of tables calculated on purpose, will be found in James Ferguson's *Select Exercises*, or in Dr. Brewster's edition of *Ferguson's Works*, vol. v. pp. 287—304.

1. *On the Line of Lines, and the method of using it.*

Each scale of the line of lines is divided into *ten* equal parts, which may be called *Divisions of the first order*. Each of these great divisions is subdivided into ten other equal parts, which may be denominated *Divisions of the second order*; and each of these is again divided by shorter lines into *two* parts, which may be called *Divisions of the third order*.

When the whole line of lines represents 10 parts, then the primary divisions represent units, and the secondary divisions represent 100th parts, and the divisions of the third order 200th parts.

When the whole line represents a 100, then the secondary divisions represent units or 100th parts of the whole, and the divisions of the third order 200th parts of the whole.

If the whole line represents 200th parts, then the smallest divisions are units, or 200th parts of the whole.

1. In order to divide a given line into any number of equal parts, for example 5, take the given line in your compasses, place one point on the 5 of one scale of the line of lines, and open or shut the sector till the point of the other foot falls on 5 on the opposite scale of the line of lines, then the distance between 1 and 1 of the same scale will be the fifth part of the given line, or the $\frac{4}{5}$th part of the given line will be the difference between the given line, and the distance of the points 4 and 4.

If the given line is too long to be applied to the sector, divide only $\frac{1}{2}$ or $\frac{1}{4}$ of it by 5, and the double or quadruple of the result will be the fifth part of the whole.

2. To form a scale of a given length to contain a given number of equal parts. If the scale to a plan

is 8 inches long, and contains 120 poles, let it be required to obtain such a scale from the sector. Having opened it, make the distance between 6 and 6 of the line of lines $= \frac{12}{2}$, equal to 4 inches ($= \frac{8}{2}$,) and the line of lines will now give the required scale.

3. To divide a line, for example, one 7 inches long into two parts of any assigned proportion, as 3 to 5, take 7 inches, the length of the line, and set it from 8 to 8 = 3 + 5, and the distances of the divisions 3.3 and 5.5 will be the parts required.

4. To find a third proportional to two given lines, for example 2 and 8, take in the compasses the lateral distances of the second term 8 from the centre or axis of motion of the sector, and setting one foot on the division expressing the first term, viz. 2, open the sector till the other foot falls on 2 on the other leg. The sector remaining in this position, take the transverse distance of 8 and 8, and this distance measured laterally from the centre will be 32, the number required for 2 : 8 = 8 : 32.

5. To find a fourth proportional to three lines, as 3, 6, and 8. Open the sector till the transverse distance of 3 is equal to the lateral distance of 6 from the centre, or some part of it; then the transverse distance will give 16, the fourth proportional required for 3 : 6 = 8 : 16.

6. To open the sector so that the two scales of lines shall form a right angle. As every triangle whose sides have the ratio of 3, 4, and 5, is a right angled one, take between the points of the compasses the lateral distance from the centre to the division marked 5, and set one foot on the division marked 4 on one of the scales of lines. Open the sector till the other foot falls on the division marked 3 on the other scale of lines, and the sector will stand at right angles to each other.

7. To find a mean proportional between two lines, for example, between 20 and 80. Place the two scales at right angles, and taking in the compasses 50, half the sum of the two lines, apply one foot to 30, the half difference, the other foot will reach to 40, the mean proportional wanted, for 20 : 40 = 40 : 80.

8. To diminish a line of 13 inches in the proportion of 6 to 5. Open the sector till the transverse distance of 6 and 6 is equal to the lateral distance of 5 and 5. Mark the point where 3 inches taken from the centre as a lateral distance reaches, and the transverse distance at that point will be the line required.

The operations of subtraction, multiplication, and division, may be performed by the line of lines; but as this process is of no utility, we shall not occupy our pages with any account of it.

2. *On the Scale of Chords, and its use.*

This is the most generally useful of all the double scales in the sector.

1. To open the sector till the two scales of chords make an angle of any number of degrees, for example, 35°. Take in the compasses the distance from the centre or joint to 35°, the proposed number of degrees, and having opened the sector till the transverse distance from 60° to 60° on each leg is equal to the distance in the compasses, the scales will make an angle of 35°.

2. To find the inclination of the two scales of chords when the sector is opened. With the compasses lay the distance from the two brass points at 60° and 60 from the centre along one of the scales of chords, and the degrees indicated will be the angle required

3. To determine the angles made by the external or internal edges of the sector, lay a straight edged ruler from 60° to 60°, of the line of chords, and having taken in the compasses the distance between the points where the edge of the ruler cuts the inner edges of the sector, lay this distance along the line of chords from its centre, and the degrees indicated will be the angle of the internal edges of the sector, which will also be that of the external edges, as these edges are respectively parallel.

Hence the sector may be used as an instrument for taking angles, by putting sights on its outer edges. It may also be used in many cases as a gaoniometer for measuring the angles of crystals.

4. To lay off an angle of any number of degrees, such as 42° less than 60°. At any opening of the sector, but the wider the better, take the transverse distance of 60° and 60° on the line of chords, and with this as a radius describe the arch of a circle. Take the transverse distance of 42° and 42°, and put this distance on the arch described. From its extremities draw two straight lines to the centre of the circle, and these lines will contain an angle of 42°. When the degrees are above 60, as 129, taking one half or one third of them, so that they may be below 60, viz. in this case $\frac{129}{3} = 43°$, and having described an arch as before, take the transverse distance of 43° and 43° from the scale of chords, and having set it thrice on the arch, and drawn lines from the extremities of the triple arch, they will form an angle of 129°.

5. To find the inclination of two given lines, describe an arch round the vertex or point of intersection, and open the sector till the distance from 60° to 60° is equal to the radius of the above arch, then taking the chord of the arch, or the distance between its extremities in the compasses, set it on each scale of the line of chords till each point of the compass falls on the said division, the degree thus indicated will be the inclination required.

6. To lay down an arch of any magnitude on the circumference of a circle. Having found the radius of the circle, open the sector till the distance of 60° and 60° be equal to that radius, then take in the compasses the chord of the given number of degrees on each leg of the sector, and lay it off on the circumference of the given circle.

By this operation a polygon of any number of sides may be inscribed in a circle. If, for example, the polygon is required to have 20 sides, then the chord of one of its sides will be $\frac{360}{20} = 18°$, which, taken as above described, and set round the circumference, will divide it into twenty parts. By joining the different points thus found, the polygon will be formed.

3. *On the Scales of Sines, Tangents and Secants, and their use.*

1. As all the scales of chords, sines, tangents, and secants are laid down to the same radius, we can o-

tain for any radius within the compass of the sector, the chord, sine, tangent and secant of any number of degrees by one adjustment of the sector. If, for example, we require them for 20°, we have only to take the given radius, and set it from 60° to 60° on the line of chords, from 90° to 90° on the line of sines; from 45° to 45° on the line of tangents, brass points being inserted at all these places, and then take from the proper scale the transverse distance of 20° to a given radius.

2. To find the chord of 80°, which is a greater number than 60°, the highest in the sector, take the transverse distance of 40° or half the arc, and lay it down twice on the circumference of a circle of the given radius, the distance between the extreme points of this double arch taken in the compasses will be the chord of 80°.

3. To find to a given radius the tangent of 70° greater than 45°, the highest on the sector take the given radius, and set it transversely from 45° to 45° on the upper scales of tangents marked 45, 50, 60, 70, 75, then take the transverse distance of 70° from the same scale for the tangent required.

4. To find the secant of an arch, for example, of 20°, open the sector till the given radius taken in the compasses is the transverse distance between 0° and 0°, or the inner termination of the scales, then the transverse distance between 20° and 20° will be the secant required. The secant of any number of degrees may be found from the line of sines thus; but this can only be done when the radius of the circle can be made a transverse distance to the cosine of the given number of degrees. Let the given radius be two inches, and let the secant of 76° be wanted. Make the radius two inches a transverse distance to the sine of 14°, the complement of 76°, then the transverse distance of 90° to 90° will be the secant of 76°.

4. *On the Line of Polygons, and its use.*

The line of polygons is placed at the two internal edges of the sector, and is numbered from 4 to 12. These lines are drawn to meet the inner lines of the line of chords, and the line of lines, and the reckoning is to be made from these lines.

1. To inscribe in a circle a regular polygon, viz. a decagon or figure of ten sides, open the sector till the transverse distance of 6 and 6 is equal to the diameter of the circle, then the transverse distance of 10 and 10 will be the side of a decagon, which may be inscribed in the circle. In the same way, any other polygon may be inscribed provided its sides do not exceed 12.

2. To describe upon a given line a regular polygon, such as an octagon, open the sector till the given line is a transverse distance to 8 and 8; then take the transverse distance of 6 and 6, and with this radius describe round the extremities of the line as centres small arcs of a circle intersecting each other. Round the point of intersection as a centre, and with the same radius, describe a circle which will of course pass through the extremities of the given line, and in this circle the octagon may be described by repeating the given line round its circumference.

The sector is an instrument of great use in dialling, in projecting solar and lunar eclipses, in the orthographic and stereographic projections of the sphere. The reader is referred for more minute information respecting its structure and use to Bion on the *Construction of Mathematical Instruments*, Robertson's *Treatise of Mathematical Instruments;* but particularly to a separate treatise on the *Compass of Proportion* by M. Ozanam.

SECTOR, DIP, the name of an instrument contrived by Dr. Wollaston* for measuring the angle of dip, or the depression of the visible horizon below the horizontal plane passing through the eye of the observer. The following very distinct description of the instrument itself, and of the method of using it, is given by Captain Basil Hall in his voyage to Loochoo.

"A perspective view of the dip sector, is shown in Plate CCCCLXXXVII. Fig. 1, and a plan of it with the telescope removed in Fig. 2. In Fig. 2, A and B represent the two reflecting glasses at right angles to the plane of the instrument, and also nearly at right angles to each other. It is clear that when the plane of the instrument is held vertically, an eye situated at E, and looking through the unsilvered part of the glass A, at a distant point C, will at the same time see by joint reflection from both glasses, another distant point D at 180° from C; and D will appear to correspond with C, if a suitable motion be given to the index glass B by the tangent screw F.

The instrument may now be supposed to measure the arc CZD. If the points C and D be each three minutes farther from the zenith than 90° the entire angle will then exceed 180° by double that quantity. The relative position of the glasses then corresponds to 180° 6′, and the six minutes of excess would be shown on the arc at F if there were no index error. But by reason of the index error, the real quantity will not be known till a similar observation has been made with the instrument in an opposite direction. If the instrument be now inverted, so that the unsilvered glass is uppermost, the arc intended to be measured is CND, or the sum of the distances of the points C and D from the nadir instead of the zenith, which of course falls short of 180° by as much as the former arc exceeded that quantity.

The difference of the two arcs is consequently twelve minutes, and if the index be now moved till the objects C and D appear to correspond, the amount of this double difference will be shown by the change of position of the vernier.

Hence it is evidently unnecessary that the index error should be previously known, and even preferable that its amount should be such as to avoid the needless introduction of negative quantities by positions on different sides of zero.

In the preceding description, it is supposed that the eye is looking directly through the unsilvered glass at the horizon, and that it also perceives the opposite horizon after two reflections; but an inspection of the figure will show that the observer's head would necessarily intercept the rays from the horizon behind him. To obviate this, both the direct and the reflected rays are received in coming from the unsilvered glass (and after passing through the field glass of the telescope) on a mirror placed at an angle of 45°, which

* See *Phil. Transactions*, 1800, 1803.

reflects them to the eye. By this ingenious contrivance, the obstruction is removed, and the opposite points of the horizon may be both seen at one moment.

In practice it is most convenient to direct the telescope to the same part of the horizon in both cases. Thus, if the east and west parts of the horizon be observed, and that the index glass be uppermost, and telescope pointing to the west, the observer is on the south side, and his face must be turned to the north. When the instrument is inverted, if the observer turn himself round at the same time, so as to face the south, then the telescope will be pointed as before to the west; but since the index glass is now undermost, the inferior arc will now be measured precisely as if his face were to the north, but with the advantage of the same lights seen in the erect position of the instrument.

In using this instrument at sea for the first time considerable difficulty arises from the constant change in the plane of the instrument from the perpendicular position, in which it is absolutely necessary that it should be held, in order to obtain a correct observation. What at first appears to be a defect, however, is a real advantage, namely, that whenever it is held in the least degree out of the vertical plane, the two horizons (that seen direct, and the reflected one) cross each other, and it is only when the plane is vertical that the horizons can appear parallel.

The object is to get the two horizons to coincide exactly, and for this purpose it will often be necessary to have them of different shades. This is managed, as in the sextant, by means of the screw, which raises or lowers the telescope. When the telescope is brought nearer to the plane of the instrument, the reflected horizon becomes dark and distinct, but when screwed off it becomes fainter, and is not so well defined. Practice alone can teach the degree of intensity which is most favourable. In general, it is best to have one horizon dark, and the other light; then bring them very nearly to coincide, and wait till the ship is steady, at which moment a slight touch of the tangent screw brings them exactly to cover one another. It will happen, of course, that when the coincidence is perfect, there is only one horizon to be seen, and a doubt remains whether all is right, but a slight motion of the instrument, by making the horizons cross each other, defines them at once.

It is advisable to take several observations, and the safest way is to take one first with the index glass uppermost, and then with the instrument inverted, after which to return to the first, and so on for two or three times each way."

SECTOR, Astronomical, the name of an instrument contrived by Mr. George Graham, for taking differences of right ascension and declination, which are too large to be observed with a micrometer in a fixed telescope. A full description of it, with a drawing, will be found in Smith's *Optics*, vol. ii. p. 350.

SECTOR, Zenith, the name of an instrument for measuring small angles near the zenith. A very fine instrument of this kind, constructed by Ramsden and Berge, has been described by Major Mudge in the Phil. Transactions for 1803, p. 383. The following abstract of this description has been given by Dr. Young.

"The external frame of the instrument is of mahogany, constituting a truncated pyramid, on a base of six feet square, tapering to a vertex of three. The internal frame, which immediately supports the sector, revolves on a vertical axis, terminating below in a cone, which rests in a conoidal cavity, convex to the axis, and above in a cylinder, passing through an octagonal aperture in the upper frame. As it turns, its motion is indicated by an azimuth circle attached to the lower part of the external frame, and it may be brought into the direction of the meridian by a telescope fixed in the plane of the arch. The telescope of the sector is eight feet long, and its aperture four inches; the axis is like that of a transit instrument, the plumb-line passes through two perforations in it, and is adjusted by means of a screw with a jointed handle, and a long bent microscope with specula, so as to bisect a point marked on a plate of mother of pearl, precisely in the axis of the instrument; this plate is properly illuminated by the same lamp that serves for the micrometer wires of the telescope, its light being reflected downwards upon the wires from an oblique surface covered with plaster of Paris.

The pivots of the sector's axis are of bell metal, they rest in Y's, firmly attached to the frame: their sliding horizontally is prevented by a fixed friction wheel on one side, and a spring supporting a friction-wheel on the other; four cylindrical braces are employed to fix the telescope firmly to the axis; and the bending of the axis is still farther obviated by levers with counterpoises, acting by means of friction-wheels, close to the tube of the telescope, so as to leave so much of the weight only to be supported by the pivots as is necessary to keep the instrument steady. The telescope is moved by strings and pullies, and is retained in any given situation by weights. A long spirit level is employed for bringing the axis into a position truly horizontal.

The arch is divided into portions of five minutes each, marked by points, on golden pins, let in at each division. A fine line was struck when the telescope was properly supported on the pivots; the instrument being then removed, the diameter of the circle, of which this arc was a part, was ascertained, and one sixteenth of this, being taken as extremely near to the chord of 7° 10′, was laid off on each side zero; and this arc was verified by comparison with another, obtained, by means of continual bisections, from an arc of 60°. The micrometer screw carries a head divided into 59 parts, nearly corresponding to seconds; the half of the arc on one side zero was found to contain only a single second more than the other portion.

The greatest error that could be observed from a difference of temperature in different parts of the observatory, was found to be little more than half a second for an arc of five degrees. The observations of the zenith distances of the various stars employed, were completed in October 1802; and the instrument was brought back to London without having sustained the least perceptible injury."

SEDLITZ Waters. See Mineral Waters.

SEGESTAN, or Seistan, an independent province in the east of Persia, bounded on the north by Candahar and Khorasan, and on the south by Mekran and Balouchistan, is 300 miles long and 160 broad. It was once one of the finest provinces of the empire, but the sand winds from Mekran and Balouchistan, which blew for 120 days during the hot months, have reduced it to the most desolate condition. The banks of the Heermund, which rising in Cabul, flows through the province into the lake of Durrah, consist of a valley from one to two miles broad, which is cultivated and covered with verdure and brushwood. On each side of it rise perpendicular cliffs, which bound the arid desert, intersected with one or two ranges of mountains, which form the rest of the province. Along the valley are great numbers of ruined towns, villages, and forts; and at one of these was Kulcauput, a noble palace in a state of good preservation. The Heermund is 400 yards wide and very deep, and its water is remarkably fine. Captain Christie describes the remains of a city called Poolkee as immense. The principal place of Seistan is Doorhak, the residence of the prince, in east long. 63° 10′, and north lat. 31°. It is situated 10 miles from the river, and is small and compact, though the ruins of it cover a great surface. It has a good bazaar, and is populous. The country round produces wheat, barley, and good pasturage. The revenues of the prince are 80,000 rupees, and his military force 3000 men. The ruins of a very large city called Peshawaroon stand 25 miles north of Dooshak; and a few miles beyond it are the ruins of Joaen. Ferrah, a large walled town 65 miles from Dooshak, stands in a fertile valley, on a river which runs into the lake Zerreh. The city of Kubbees, about ten days journey from Dooshak, stands in the midst of the arid plain above mentioned, fifteen days journey from Kerman, and sixteen from Yezd. See Kinneir's *Memoir of the Persian Empire*, p. 189—194.

SEGNA, a free sea-port town of Morlachia, under the protection of Austria. It stands on the Adriatic, at the mouth of a narrow valley, surrounded with marble hills. It is ill built, ill paved, and ill fortified, and is exposed to such violent winds from the mountains, that the sea in the channel of Segna, opposite the valley, is seldom calm. The soil scarcely supplies provisions for two months of the year, and water is brought from a spring twelve miles distant. Such a city, therefore, cannot prosper, and yet it is said to contain 6000 souls. East long. 16° 3′, north lat. 45° 4′.

SEGO. See Africa, and Bambara.

SEGOVIA, a town of Spain, in Old Castile, and capital of a province of the same name, is situated on a rocky eminence between two steep valleys, one of which is watered by a brook called Clamares, and the other by the river Erosma, which is crossed by five handsome bridges. It is supposed to resemble a ship with its stern to the east. It is between three and four miles in circuit, and is surrounded with a turreted Moorish wall. The streets are narrow, crooked, and irregular, and in some places steep, but the suburbs are built on more level ground.

Segovia, which is an episcopal see, contains a number of churches and convents, and other public buildings. The Mint is a handsome edifice, the operations of which are carried on by hydraulic machinery. The town-house is handsome, having two compartments in front, with double rows of doric pillars. The cathedral is a mixture of Gothic and Greek architecture. It was built in the 16th century, and has its principal altar of marble. The convent of the Carmelites, and that of the Capuchins, with a subterraneous chapel, are good buildings. The alcazar, the residence of the Castilians, and celebrated as the place where Alphonso composed his astronomical tables, is a venerable ancient pile, containing apartments fretted with Mosaic work still fresh.

The greatest curiosity of Segovia is its aqueduct, which, though supposed by some to be Egyptian, is more probably the work of Licinius or Trajan. It begins with a large stone basin, fifty yards from the town, the water of which it conveys to an open canal to the streets. It is built of rough square freestones, with cement, and consists of a long range of 75 arches, the first of which is fourteen feet six inches long, and the last, at the convent of St. Francisco, thirty-three feet six inches. At this place there begins a double row of arches, one above another, extending east and west, and crossing the valley and the plain of Azoquejo. The greatest height of this is eighty feet ten inches. The whole aqueduct contains 159 arches, sustained by pilasters, most of which are six feet eleven inches in front, and nine feet four inches on the inner side. After distributing its water to different parts of the town, the aqueduct terminates at the Alcazar. The magnificent appearance of that fine building is disfigured by houses built against its pilasters. This city, situated in the midst of the finest sheep pasturage, has been long distinguished for its cloth and woollen manufactures. It is said that 34,000 persons were once employed in them, but they have greatly declined. The quantity of cloth at present manufactured is stated to be about 4000 pieces, coarse and fine. Dyeing is also extensively carried on, and delft ware, paper, and lead, are among its other manufactures. It has an extensive trade in wool, which is brought from Villacastin, and sent to different ports, particularly Bilboa. The number of families is estimated at 5000, and the population at only 10,000. There is an artillery school, and several hospitals in the town. West long. 4° 1′ North lat. 41° 3′.

SEINE, the name of a department in the north of France. It embraces little more than Paris, the capital. It includes three arrondissements, viz. Paris, St. Denis, and Sceaux, forming a square of about sixteen miles. The population is 70,000, exclusive of Paris, which contains, according to the census of 1827, 890,431 inhabitants.

SEINE, Lower, the name of a department in the north of France, containing the north east part of Normandy. It is bounded on the N.W. by the English channel, on the east by the departments of the Somme and the Oise, and on the south by that of the Eure and the Calvados, from both of which the river Seine divides it. It occupies about 2500 square miles. Its surface is generally level or undulating. The coast consists of sandy downs, and the soil, though generally suited to corn and pasture, does not favour the culture of the vine. Hemp, flax, and coleseed are cultivated. Black cattle, horses, cheese and butter, are exported. The principal fruits are pears and apples. The Seine, the Argens, and the Bresle, are the principal rivers. The chief towns are Rouen, the capital, Dieppe, Havre de Grace, Yvetot, and Neufchatel. The contributions in the year 1803 were 9,104,417 francs, and its expenses 570,526. The population in 1827 was 688,295, being an increase of 32,491 since 1822.

SEINE and MARNE, one of the departments in the north of France, bounded on the north by the departments of the Oise and the Aisne, on the east by that of the Marne and the Aube, on the south east by those of the Yonne, on the south by that of the Loiret, and on the west by those of the Loiret and the Seine and Oise. It occupies about 2300 square miles. Its surface consists of gently undulating plains, which produce wheat, barley, oats, flax, hemp, and wines in small quantities. It is watered by the Seine, the Marne, the Yonne, the Great and Little Morin, and several smaller streams; the canal of Briare, which joins the Seine and the Loire crosses the southern part of it. (See NAVIGATION INLAND.) Its chief towns are Melun, the chief place, Fountainbleau, Meaux, Provins, and Coulomiers. The contributions in 1803 were 5,126,616 francs, and the expenses 307,818. Its population in 1827 was 318,209, being an increase of 15,059 since 1822.

SEINE and OISE, a department in the north of France, bounded on the north by the department of the Oise, on the east by that of the Seine and Marne, on the south by that of the Loiret, and on the west by those of the Eure and the Eure of Loire. It occupies an area of 2200 square miles, which are level or gently undulating. It produces wheat, barley, oats, hemp, and flax, but vines are raised in small quantity. The chief rivers are the Seine and the Oise. The principal manufactures are those of porcelain at Sevres, of calicoes at Joui, and of arms and clocks at Versailles. The most important towns are Versailles, the chief place, Etampes, Mantes, Pontoise, Corbeil, and Rambouillet. The contributions in 1803, were 7,373,685 francs, and the expenses, 448,928. Population in 1827, 440,871, being an increase of 16,381 since 1822.

SEISTAN. See SEGESTAN.

SELBY, anciently SALEBIA, a market town of England in the west riding of Yorkshire, is situated on the south or right bank of the river Ouse, which is crossed by a very handsome wooden bridge, which opens for the admission of vessels into the river, which is here navigable for ships of burden. It consists of three streets in the shape of the letter Y reversed. The principal one, beginning at the foot of the bridge, is the road to Leeds, and the other leads to Snaith and Thorne. The ancient and ill-built houses of the town are now replacing by those of more modern aspect. The church, which formed part of the abbey founded by William the Conqueror, is of various styles of architecture. The body and the nave are Norman. The church has the form of a cross, the shaft of which is 267 feet long, and its transept 100 feet. The principal manufactures in this place are those of ships, leather, sail-cloth, and iron goods. A very considerable trade in vessels of good burthen, has been created with London, Hull, and Lynn, by means of a canal from the Ouse to the Aire. Number of houses in the town and parish 840. Population in 1821, 4099. See the *Beauties of England and Wales.*

SELDEN, JOHN, honoured by Grotius with the appellation of the "Glory of England," was an eminent scholar and politician. He was born at Salvington in Sussex in 1584. He was educated at Chichester, and after studying four years at Oxford, he entered the inner temple, where he acquired great reputation by his learning.

His first work was entitled *Analekton Anglo Britannicon*, a chronological summary of English history down to the conquest. This was followed by *England's Epinomis* and *Jani Anglorum Facies Altera*, a Latin and English treatise on the origin and progress of English law. His largest English work, a treatise on *Titles of Heroism*, which appeared in 1609, obtained him great fame; and in 1617 he entered upon a new field, and made himself known throughout Europe by his work *De Diis Syris*, a work of great learning and research.

The next work of our author's was a *History of Tythes* published in 1618, in which he opposed the claim of divine right to tythes made by the clergy of those days, and therefore exposed himself to the hostility of that body. He was accused before King James, and being called before the Archbishop of Canterbury, he was induced to sign a declaration of his regret for what he had done. This event seems to have prepared him for that resistance to civil tyranny, which formed a striking feature in the rest of his life.

In the contest between the king and the parliament which he assembled in 1621, Selden was a leading agent in drawing up the splendid remonstrances of that body. He accordingly fell under the royal resentment and was committed to prison. Being discharged on his own petition, he resumed his peaceful pursuits, and published in 1623, the historical work of Eadmer of Canterbury.

In 1629, he was elected one of the members of parliament for Lancaster, and he also enjoyed a seat in that house in the two first parliaments of Charles I. In the second of these parliaments he was appointed to support articles of impeachment against the Duke of Buckingham. He afterwards took up the cause of Sir Edward Hampden; and in 1628, he was employed by the House of Commons to justify by facts its resolution respecting the right of the subject to his liberty and property. Amid these engrossing pursuits, he found time to compose his *Marmora Arundeliana*, which appeared in 1627.

On the dissolution of parliament, Selden was one of the eight members of the House of Commons, who were thrown into the Tower, on a charge of sedition. Having refused to purchase his freedom by the slightest submission, he was removed to the Marshalsea prison, and then to the Gatehouse, and, along with his companions, was allowed to go at large on bail till 1630, when they were fully liberated.*

During this confinement, Selden composed his work, *De Successionibus in bona Defuncti ad Leges Ebræorum*, which appeared in 1631, and was reprinted in 1636, with a new treatise *De Successione in Pontificatum Ebræorum.*

A dispute having arisen with the Dutch respecting the herring fishery on the British coast, Selden was induced by Archbishop Laud to draw up his treatise, entitled, *Mare Clausum Seu Dominio Maris*, and another to the work of Grotius, entitled *Mare Liberum*. King James read and approved of this work, which appeared in 1635, and the object of which was to prove, "that the British have an hereditary uninterrupted right to the sovereignty of their seas, conveyed to them from their earliest ancestors in trust for their latest posterity."

Having for some years devoted most of his time to

* About fifteen years afterwards the Parliament allowed Selden £5000 for the losses he sustained from this treatment.

Hebrew literature, he published in 1640 his work *De Jure Naturali et Gentium juxta Disciplinam Ebreorum*, which contains a copious digest of the laws and institutions of the Jews.

In 1640, Selden was chosen one of the representatives of the university of Oxford to the long parliament. He took an active part in reforming the abuses of the day, but he was well affected to the constitution both in church and state, and he opposed the violent attempts of both the contending factions. In 1643, he was appointed by the House of Commons keeper of the records in the Tower, and likewise one of the lay members of the Westminster Assembly of divines.

From this period till the time of his death, our author published the following works.

Eutychii Ægyptii Origines Ecclesiæ suæ, a translation from the Arabic.

De Anno Civili Veteris Ecclesiæ uxor Ebraica.

An edition of *Fleta.*

De Synedriis Veterum Ebræorum.

Vindiciæ de Scriptiore maris clause, which was the last production of his pen.

Selden died in 1654, in the seventy-first year of his age, and was interred in the temple church, where a monument is erected to his memory.

His works have been collected and published in 1726, in three vols. folio, with a life of the author in Latin, by Dr. David Wilkins.

SELENOGRAPHY, from σεληνη *the moon*, and γραφη, *a description*, is that branch of astronomy which treats of the lunar surfaces. See our article ASTRONOMY, Vol. II. p. 623, 636, for very full details respecting this curious subject, and also Ferguson's *Astronomy*, edited by Dr. Brewster, App. vol. ii. Since these details were published, Professor Lohrman of the military academy of Dresden, has published an atlas of lunar maps, which represent the whole visible surfaces of the lunar globe, with an accuracy and precision beyond any thing that has yet been attempted. See Dr. Brewster's *Journal of Science*, January, 1825, vol. ii. p. 172.

SELEUCIA, an ancient city of Asia, built by Seleucas, one of Alexander's generals, about forty-five miles north of ancient Babylon, and on the west bank of the Tigris.

Suadea, the port of Antioch, and about four miles distant, is considered by Browne the African traveller, as identical with Seleucia, while Mr. Jackson, author of the "Journey from India," regards Bagdad as the site of the ancient Seleucia; several coins of Seleucas having been found in that city. A description of Suadea will be found in Brown's *Travels in Africa*, p. 391.

SELKIRK, ALEXANDER, the name of a celebrated Scottish traveller, whose adventures form the subject of Robinson Crusoe, was born at Largo in the county of Fife, about 1676, and was brought up to the profession of a sailor. As sailing master of the Cinque Ports galley, he left England in 1703, and in September of the same year, he set sail from Cork in company with the St. George of twenty six guns, Captain Dampier, with a view of cruising against the Spaniards in the South Seas. Pickering, the captain of Selkirk's ship, died on the coast of Brazil, and was succeeded by Lieutenant Stradling. From Juan Fernandez, to which they proceeded after doubling Cape Horn, they were compelled to fly by the sight of two French ships of thirty-six guns each, and left on the island five of Stradling's men, who were taken by the French.

Dampier and Stradling having separated on the coast of America, in consequence of a quarrel in May 1704, Stradling returned to Juan Fernandez in September. Here Selkirk and he had a quarrel, in consequence of which the former resolved to remain on the island.

When the galley was about to leave the island, Selkirk's resolution began to fail, but though he requested Stradling to receive him on board, this inhuman officer denied his request, and left him behind, with his clothes, some bedding, a gun, with a little powder and ball, and a few books, and mathematical instruments.

In this solitary situation, "the monarch of all he surveyed," he was seized with melancholy, and often resolved to put an end to his life. After enduring this species of wretchedness for 18 months, his mind began to reconcile itself to the sadness of its condition, and he chased away the weary hours by building huts and hunting the wild goats of the island. He amused himself with training young kids and other animals as his companions, and when his drapery had lost its folds, he replaced it by the skins of the goats whose flesh had served him for food. In this desolate condition Selkirk spent *four years* and four months. During that time he had caught 1000 goats, half of whom he had set free after slitting them in the ear.* While pursuing a goat with great eagerness, he caught it at the edge of a precipice, over which he fell through a great height. After lying, as he computed, three days senseless, he recovered, and found himself so much bruised, that he was scarcely able to crawl to his habitation. The only other adventure which happened to him was the arrival of a Spanish ship, the crew of which saw him at a distance. Dreading, however, to fall into their hands, he exerted himself to escape, and, by climbing a tree with much foliage, he succeeded with great difficulty, after having been shot at by the Spaniards. On the 2d February 1709, Selkirk was delighted with the sight of two ships approaching the island. Having recognised them to be English, he lighted a signal fire, and he had even the happiness of finding that they were English privateers, the *Duke* and the *Duchess* from Bristol, commanded by Captains Rogers and Courtney. Selkirk was kindly received by his countrymen; and, after continuing a fortnight at the island, they all embarked, and sailed by the way of the East Indies for England, where they arrived on the 1st October 1711; after plundering a town on the coast of Persia, and taking a Manilla ship off California. During this cruise, Selkirk was appointed by Captain Rogers master's mate of the *Duke*. Although Selkirk had performed his devotions with great regularity yet his language had become scarcely intelligible when he was first taken from the island. The curiosity of the public having been greatly excited by the narration of his extraordinary adventures, Selkirk put an ac-

* Thirty years afterwards, Commodore Anson said that the first goat which was shot, had a slit in its ear, and was, therefore one of Selkirk's.

count of them into the hands of that celebrated writer Daniel Defoe, who, in place of publishing them as a true narrative, made them the ground work of the interesting story of Robinson Crusoe. The future history of Selkirk is not known, but so late as 1798, the chest and musket which Selkirk had with him on the island of Juan Fernandez, were in the possession of his grand-nephew, John Selkirk, a weaver at the village of Largo.

SELKIRK, a royal burgh of Scotland, and capital of the county of the same name, is finely situated on a commanding eminence below the confluence of the rivers Yarrow and Ettrick, and about 1½ mile above the junction of their united streams with the Tweed. This town has of late been greatly improved, and contains several good houses. The principal buildings are a new town-house, with a handsome spire and clock, and containing apartments for the Sheriff court and the business of the burgh. A new prison has been erected at the back of the town. It is encircled with a lofty wall, which incloses an area accessible to the prisoners. The other buildings are the parish church and the Secession meeting-house. The principal manufactories here are an inkle one, which has been long established, and a tan-work; and the making of stockings and the spinning of woollen yarn are carried on to a considerable extent.

This burgh has been celebrated by the devoted bravery of its citizens at the battle of Flodden. Of 100 who followed James IV. to the field, only a few survived. A standard taken from the English on the occasion, by a member of the corporation of weavers, is still in their possession; and the sword of William Brydone, the town clerk, who led the citizens to the battle, and who was knighted for his valour, is still in the possession of his descendant, an inhabitant of Selkirk. The English were so exasperated at the bravery of that band of citizens, that they laid Selkirk in ashes. James V. however, in reward of their eminent services, granted them a thousand acres of Selkirk Forest, which are now worth about L.1500 per annum, and are divided into a great number of small properties. In their annual survey of this tract, the English standard is carried before the corporation of weavers.

A battle was fought on Philiphaugh, opposite to the town, on the 15th September, 1645, in which General Lesly completely defeated the Marquis of Montrose.

Selkirk unites with Peebles, Lanark, and Linlithgow, in sending a member to Parliament. The town is governed by two bailies, a dean of guild, a treasurer, and 29 councillors, in all 33. The revenue derived from three large commons, mills, feus, and other sources, is about L.1000 annually.

The vicinity of Selkirk, towards the united streams of the Yarrow and Ettrick, is beautiful; and a fine view of it is obtained from the town. The chief object of interest here is the ruin of Newark Castle, situated on a peninsula formed by the Yarrow, which has cut its course through rugged rocks enveloped in wood. Haining, the seat of John Pringle, Esq. of Clifton, is situated close to Selkirk; and Yair, the seat of Alexr. Pringle, Esq. of Whitebank, situated on the banks of the Tweed, is celebrated for its picturesque beauties. Sunderland Hall is beautifully situated at the junction of the Tweed and the Ettrick, about two miles below Selkirk.

SELKIRKSHIRE, or Ettrick Forest, lies nearly in the middle of the southern division of Scotland. It is bounded on the north by Peeblesshire and Mid-Lothian; on the east by Roxburghshire, on the south by the latter and Dumfriesshire, and on the west by Peeblesshire. The boundary line on the west and south is very irregular, Selkirkshire being dovetailed into the neighbouring counties in these directions in the most unaccountable manner. From this cause, although it is one of the least counties in the kingdom, its greatest length and breadth are considerable. From Phawhope Pen, a high mountain at the source of the Ettrick, to the heights of Caddon water, on the north-east boundary, is nearly 30 miles; and from Borthwickbrae to the foot of Glensax, where it reaches within a short distance of Peebles, may be nearly 20. Yet it contains only about 260 square miles, or about 166,000 acres.

This shire is divided, according to its natural features, into three dales or valleys, by two ridges of mountains running N.E. by E. but diverging as they retire towards the west, and an undulated flat muir falling from the southern heights of the Ettrick towards the water of Borthwick; the upper part of which is green hill pasture, and is mostly included in the county. The water of Ale, with some tributary streams, rises in this muir from many small lakes. On all this side of the Ettrick there are no hills of any great height, and the ground is much covered with heath. The higher elevations on the middle ridge between the Ettrick and Yarrow reach from 1700 to nearly 2000 feet above sea level. The northern ridge between Yarrow and Tweed is more lofty, and has of course a wider base, and the diverging and minor valleys are of greater extent. Besides these, Selkirkshire is properly surrounded from the north-east to the south by a range of mountains that form part of the great central chain that sinks into the sea between East Lothian and Berwickshire. Many of these rise to a height considerably above 2000 feet. Through these mountains, the Tweed issues from Peeblesshire, or Tweeddale, leaving on its right Blackhouse heights, and passing on its left under Windlestrae Law; the one 2370, and the other nearly 2300 feet above the sea. These mountains extend towards the south, and cover the sources of the Yarrow and Ettrick. As the two minor ridges, before mentioned, branch off, their character is changed, and they form around the winding lakes of St. Mary a mingled group of lofty hills, smooth and round, and clothed with herbage, the fine green of which refreshes and delights the eye. All this, connected with the embosomed lakes, gives to them in a summer evening a singular character of softness and quietude and pastoral beauty almost peculiar to the district. In winter, when covered with undrifted snow, the scene rises towards grandeur and sublimity. As there are no rocks, the pure white of the splendid envelope is unbroken, there is nought save the majestic forms of the mountains, and their azure shadows to arrest the eye, and from different eminences to the northward, the view can never fail to be deeply impressive on a mind capable of enjoying the silent sublimity of nature. It is likely Burns had this scene in his mind when he wrote

While maniac winter rages o'er
The hills, whence classic Yarrow flows,
Rousing the turbid torrents roar,
Or sweeping wild a waste of snows.

The main river is the Tweed, (see PEEBLESSHIRE.) which flows through the northernmost of the three valleys for ten or twelve miles. This, although not the richest, is, to a traveller, the finest part of the country. The river itself, with its "crystal streams," often fringed with trees, is beautiful, and its lively and murmuring current has a cheerful effect. The hills rise more abruptly than elsewhere, and are ornamented with almost enough of natural wood, extending with little interruption along the skirts of the southern hills, while old hollys, hawthorns, and ashes, the hardy remains of a former race, are scattered among the rocks and shingle, along the steep declivities of those on the north. Besides, the picturesque ruins of the old baronial castle of Elibank, and four or five gentlemen's seats, each of different styles of beauty, greatly tend to soften the wildness of this mountainous valley. As one ascends the Tweed, below its junction with the Ettrick, by a sudden turn of some miles to the south, it seems to fall into, and be subsidiary to the valley of the lesser river; the Ettrick by its direction towards the southwest appearing to be a continuation of the strath of the Tweed.

The length of the Ettrick to its highest source is about 30 miles. For the first ten or twelve, the banks of the water are partially covered with natural wood, mixed with plantations, and now and then even scattered remains extend to the sides of the hills. This alternation of wood and pasture, and arable fields, with the town of Selkirk overhanging the river on the south, Bowhill, a fine seat of the Duke of Buccleugh's, on the slope of a mountain that divides it from the Yarrow on the north, one or two old towers, and the excellent cultivation of the haughs and lower grounds, give this part of the valley a character of varied beauty and richness. The valleys of most of the tributary rivers in Scotland, at their junction, are bounded by mountains that are dry, healthy, and comparatively barren; and such are those separating the Ettrick and the Yarrow, and between the latter and the Tweed. The middle and upper part of the valley of Ettrick is perhaps the most beautiful pastoral district in the kingdom. The hills are almost without exception of the finest deep-green mountain pasture, on which are spread thousands of sheep, and for many miles the valley opens into wide haughs of great fertility, where are seen many herds of fine cattle.

The head of the Yarrow is properly formed by several glens, and slopes, and cleughs, that open upon St. Mary's Loch and the Loch of the Lowes, and send their streams to supply its waters. The principal of these is called Meggat. It is a dark valley, having all the characters of a wild deep highland glen rising by numberless sources among the highest summits of the great range already mentioned. It flows into St. Mary's Loch through a tract of fine meadow land, the hills on each side of which are skirted with bushes and old natural wood: but it is altogether in Peeblesshire, the shore of the lake forming the boundary line for a little way. After leaving those beautiful pieces of water, Yarrow flows among hills and cultivated haughs, where there is little of the picturesque for eight or nine miles, yet it is similar to the Ettrick in its general character. It has more heath on the hills, and fewer haughs in the valley: but its hills are likewise green, and its haughs are fertile, and for several miles, it will yield to few waters* in Scotland in varied and romantic beauty, until it joins the Ettrick below the castle of Newark, and Bowhill already mentioned, which is situated in view of both waters. Through most of this part of its course it dashes through a rocky channel, while its banks and the sides of the surrounding hills are covered with fine natural wood, and a magnificent extent of old pines and forest trees.

The water of Ale belongs to Roxburghshire, but it draws its sources from a number of small lochs in the extensive muirs between the Ettrick and Borthwick. These lakes are mostly full of shell marl, and of great value, had they lain near the cultivated country. It may be mentioned as not a little curious, that they have all the Westmoreland appellation of *mere* or *muir*, as it is here pronounced, attached to their names: as Kingsmuir loch, Alemuir loch, Akermuir loch, Hellmuir loch, &c.

Borthwick, in its upper course, belongs to both Selkirkshire and Teviotdale. It rises like the rest among green grassy hills, on the borders of Dumfriesshire. Rankleburn rises contiguous to the Ale and the Borthwick, and has a claim to notice only because there is situated the farm that gives a title to the duke of Buccleugh, the proprietor of two-thirds of the county.

Gala runs for twenty miles through Mid-Lothian, and only bounds Selkirkshire for a few miles before it joins the Tweed. This part of its course is well wooded and beautiful, and as it runs through and drives the machinery of the village of Galashiels, it probably conduces more to the wealth and industry of the district than all the rest.

The lowest part of the county at the side of the Tweed, is nearly 300 feet above the sea. The county town, and Thirlestane castle, and St. Mary's loch, are all 560. The highest farm house on the Ettrick is more than 700, so, as may be expected, the climate of Selkirkshire is wet, boisterous, and stormy; and although protected on the west by a high range of mountains, yet the west and south-west winds rage with much violence, generally bringing rain to the greater part of the district. As most of the lesser rivers run towards the east and north-east, the cold winds from these points blow up the valleys with little obstruction.

The following is the average of seven years, abstracted from a very accurate register of the weather kept at the farm house of Bowerhope, on the north side of St. Mary's loch. The height above the sea is, according to Ainslie, 560 feet. It is to be regretted that a register of the thermometer is not included. Along with the register is kept a memorandum of the first appearance and flowering of several of the deepest rooted plants, and the first appearance of frog spawn.

* Only a few rivers in Scotland get the name of *river*; they are universally called waters, except the Tweed, the Forth, the Spey, the Clyde, &c.

	W.	S. W.	N. W.	E.	S.E.	N. E.	N.	S.	Days fair.	Rain.	Snow.	Annual average of the barometer.

On the 26th of February 1810, the barometer stood at 30.8, and on the 20th December 1821, it stood at 27.8.

The following is from a register kept at Tinnis, about eight miles down the Yarrow, and 60 feet lower. Therm. at 8 A. M. and 10 P. M.

For the year 1827.

Fair days.	Rain and snow.	Mean heat.	Mean of barometer.
171	194	44.23	29.12*

At Thirlestane castle, on the banks of the Ettrick, and about 650 feet above the level of the sea, a very accurate register of the thermometer has been kept by Lord Napier since 1821, of which the following are the results. Thirlestane castle is situated in W. Long. 3° 9′, and in N. Lat. 55° 26′.

	Mean Temp.	Mean temperature of Winter.	Spring.	Summer.	Autumn.
1821	44° 9	36°	42° 3	54° 3	47° 3
1822	45° 4	36° 3	43° 9	56° 9	44° 9
1823	43° 7	35° 3	41°	52°	46° 5
1824	42° 2	35° 7	39°	52°	42° 3
Mean	44° 05	35° 8	41° 55	53° 8	45° 25

Frosty mornings are prevalent even until the first of June, and it is only in rare seasons that the early varieties of apples and pears ripen properly. But in the valley of the Tweed, and the vicinity of Galashiels, which is lower and better sheltered, the temperature is greater; here there is less rain than its elevation and mountainous neighbourhood might seem to warrant, and of late years, when the summers have been warmer, plumbs, peaches, and even nectarines, have come to good flavour. However, there are reasons for thinking† this may be attributed to the superior care and cultivation of modern times.

Around Selkirk and Galashiels, even the hills are subjected to the plough. Here wheat is raised even as a considerable part of the rotation; and such has been the improvement in the cultivation of the "golden grain," and so well is every process of its management now understood, that it has often been raised 60 lbs. per Winchester bushel, 700 feet above sea level. Mildew is of rare occurrence, and smut is considered a proof of carelessness, and is still more seldom to be seen.‡

In the upper valleys of Ettrick and Yarrow, tillage is confined to the haughs and low ground contiguous. Although the attention is chiefly devoted to sheep and cattle, yet as most of the farmers must keep a pair of horses to drive fuel, and secure their crops of hay, they find it profitable and more convenient to have between 20 and 30 acres in a rotation of turnips, barley, hay, and oats, which otherwise might perhaps be more economically kept in pasture, for which the moisture and lateness of the climate renders it better adapted. Yet in favourable seasons, more luxuriant crops are nowhere to be met with; and, indeed, throughout the county generally, agriculture is as well understood and practised as in any district of the kingdom.

A small stout breed of horses was common to Selkirkshire and Teviotdale in former times, some of which were capable of great action, and which, it may be regretted, have been superseded, during the last fifty years, by crossing with horses from Lanarkshire, and in consequence, those now used for the plough much resemble that breed, but not so weighty and powerful.

There is an excellent breed of cattle, but more fit "for feeding than for milk," it having been the custom for many years past to purchase the bulls from Northumberland, of a breed perhaps too fine for the wet climate, and exposed pastures. Dairy farming is not practised.

Between fifty and sixty years ago, the blackfaced sheep, with coarse wool, were general, excepting on a few of the lowest farms near the meeting of the rivers, and they were for some time totally changed for the Cheviot breed. In 1798, when Dr. Douglas wrote his excellent survey, the whole number of sheep in the county were about 118,000, of which 36,000 were then blackfaced. Ten years ago there were none. Of late, a few farmers have again had recourse to them, as the low price has rendered the wool (the original cause of their banishment) of less consequence; and on the most upland farms, they are now confessed to be a surer and more profitable stock. There are at present about 2500 of the original breed, and they are likely to be increased. In the meantime, great attention and skill is directed to the improvement of both kinds; and this has been stimulated and kept up principally through the benevolent and patriotic exertions of Lord Napier, who, at the end of the war, returning from sea, rebuilt the "mountain home" of his ancestors, and betook himself to sheep-farming, as a rational amusement. By his lordship's influence, a pastoral society was formed, which is very numerous, including many from the adjoining districts. It has a great annual meeting, and distributes premiums for the best cattle and horses, as well as sheep. It may now safely be averred, that in no district of Scotland is so much skill and care directed to sheep farming. Perhaps, in some respects, this has been carried too far. A great proportion, particularly of the western part of the county, consists of a deep soft

* The barometer used here was one with a wheel. † An old tune.

‡ The consumption of this grain has so greatly increased, that whereas forty years ago, only two loaves came weekly into the parish of Ettrick, one to the manse, and the other to the principal farm house, now three carts with wheaten bread arrive weekly.

clay along the slopes of the hills, and forming the bottom of the narrow valleys. For almost one half the year, this kind of soil was formerly surcharged with water, and it was never in a dry state. A kind of rush called *sprett*, and a *scirpus* called *pry*, (*juncus articulatus* and *scirpi*, var. sp.) occupied the ground almost exclusively. These sloping bogs were carefully drained, and another kind of herbage took possession. But the *pry* is an evergreen, and the *sprett* begins to spring in the end of April; and so they were found when most wanted. Again, it was discovered that the moles with which the rich dry green pasture was overrun, and annually *topdressed*, became partial to the newly drained bogs, and tapped the dams, and let out the water. Mole-catchers were introduced from Lancashire; and in twenty years, a mole became as rare as a hedgehog. Some of the old people go the length of saying, that since the bogs were drained, and the moles destroyed, their farms have neither kept so many sheep, nor fed such fat lambs as formerly. Moreover, a vexatious disease has, within the same period, been gradually increasing,* ascribed by many to the above causes. But we have not room to be more minute, although the subject is both curious and interesting in many respects.†

The transition series of rocks, and that of remarkable uniformity, prevails throughout the whole of Selkirkshire. It is entirely schistose, consisting of gray wacke and slate, with one interesting exception to be afterwards mentioned.‡ The stratification is regular, on a great scale, running ftom S. W. to N. E. with various dips. At Newhouse Lynns, about seven miles above Selkirk, where the Ettrick has cut its way through the barrier of an ancient lake to the depth of a hundred feet, the thin strata of gray wacke and soft slate is bent to a curve of more than 220°. The same phenomenon is to be observed on the Yarrow below Newark, in the direction of the strata, and about four miles distant. Near the junction of both rivers, the gray wacke contains so much iron that it is of a brownish yellow for a thickness of 800 yards or more. The town of Selkirk is partly founded on another variety, containing many veins of heavy spar. Mountainous masses of feldspar and feldspar-porphyry rest upon the schistose rocks near the junction of the formation. These masses reach nearly in one direction from St. Abb's Head to near Selkirk; but do not enter the county. Dirrington Laws and Colding Knolls in Berwickshire, and Eilden Hills and Whitelaw Kips, consist of this rock.§

A curious anomaly occurs in the N. W. of the county. Along the lofty range already mentioned that separates it from Peeblesshire, there run thick strata of beautiful porphyry of various shades of colour, from nearly blood-red to brownish yellow. It is observed first overlying the clay slate that has been long wrought for sale at Grieston, a mile west from Traquair. The direction is through the centre of Windlestrælaw. The schistus and it continue overlying one another for a distance of nearly three miles across; the most southerly porphyry being near Hollylee. But what renders this more interesting, there is found alternating, with this porphyry‖ thin strata of flinty slate, clear gray porphyry, gneis, and granite. Now stratified granite is mentioned by Professor Playfair, as having been discovered by Sir James Hall and himself in Fasnet Water in Lammermoor, and he mentions it as having been found likewise at Loch Ken in Galloway. There is therefore great probability that the granite and gneis of these three places are a continuation of the same strata, for the intermediate point is nearly in a line with the other two, and not far from the line of direction of the under and overlying slate and gray wacke. The flinty slate has been observed in glens connected with the head of the Yarrow in the requisite direction. Both the latter and the gray porphyry are of great hardness; the porphyry ringing like metal when struck on a large block, and taking a high polish, and the slate giving fire with steel. Sometimes the gray wacke runs into amygdaloid, and veins of black carbonaceous slate, intermixed with pyrites, occur in divers places. Pieces of insulated galena have been found in the course of the porphyretic strata near Traquair, and trials to find lead have been made repeatedly without success. A considerable quantity of ore of antimony was found in digging a well at Traquair manse. No limestone has yet been discovered, but in two or three places there are springs supersaturated with carbonate of lime, and generally in lines, indicating, that in their way to the surface they pass over considerable masses of calcareous rock.

Probably owing to the uniformity of the rocky structure, the botany of the district is likewise very uniform. Notwithstanding that the mountains rise to a considerable elevation, few alpine plants are found. The *Rubus Chamæmorus* is plentiful in several places in the massy hollows between the higher summits, *Sedum telhephium*, *Saxifraga stellaris* and *Oppositifolia*, are met with near the limits of the country with Dumfriesshire. The more rare plants in the district are *Circea alpina*, in the shingle on S. E. verge of St. Mary's Loch, *C. lutetiana*, near Gleddes-weel on Tweedside; *Trollius Europeus*, and *Cnicus heterophyllus*, in a bushy cleugh falling into Douglas burn; *Drosera rotoundifolia*, in Deucher hope; *Thalictrum alpinum*, at Newhouse lynns; *Sedum villosum*, Douglas burn; *Hydrocotyle vulgaris*, below Oakwood; *Melampyrum sylvaticum*, in Newhouse-bank and on Glen heights.

The remains of the ancient natural woods, of which, including the bosky cleughs in the uplands,

* First known in Ayrshire, where it is called *vinkish*, and on the Cheviot, where it is called *pining*, from the slow and sure wasting of the animal.

† In the meantime, quarter has been granted to the moles. Several who had made agreements with the mole catchers continue to pay them, but refuse to let them work; and one or two farmers have begun partially to reinundate their boggy land.

‡ The red free stone of Roxburgh and Berwickshire reaches no farther up the Tweed than to near Old Melrose.

§ A quarry was lately cut into the steep declivity on the S. W. point of these hills, when the rock was found to be crystallized pentagonal prisms, perpendicular to the horizon, and about fifteen inches diameter. The pillars are extremely beautiful and elegant, the angles being sharper than any basaltic pillars we have seen, and of a pale flesh colour. The height laid bare as yet is only about twenty feet, but as the declivity is great it would require but little expense to uncover more than double the present length of the columns which probably may reach the sparry schist upon which the mountain reposes.

‖ These are strata of granite gneis, and are observed in Priesthope, a deep glen on the south side of the Windlestrælaw.

there is not more than 600 or 700 acres in all, are made up of oak, ash, elm, (*montanus*,) birch, alder, hagberry, (*P. padus*) holly, sloethorn, hawthorn, hazle, mountain ash, aspin (rare) ivy, honeysuckle, and four or five species of roses, and a number of willows. Sometimes a solitary mountain ash has outlived its cotemporaries, and is found overshadowing a rocky cleugh, 1500, and in one solitary instance, even near 2000 feet above sea level. Travellers who attend to such matters have often been struck with the numbers of large and ancient hollies which remain along the steep and shingly faces of the hills on the north side of the Tweed, from Yair to Hollylee, with here and there a hawthorn, seemingly of equal duration, where a modern hedge of either could hardly be raised in a lifetime even with great trouble and expense.

Since the draining of the bogs along the sides of the higher valleys, which were covered formerly with *Juncus articulatus* and *carices*, these plants have given place to *Aira cespitosa* and some *Agrostidæ* on the clay, and groves of tall *Carduus Palustris* on the mossy ground. The latter is a valuable acquisition to the sheep in late springs, when they scoop out the roots even an inch or two below the surface; but the former although an evergreen, they seem to refuse on such soils as this altogether, probably because it has got up with too rank luxuriance. As a remedy, some farmers have tried burning it in spring, some mowing in early summer for hay, and some have stopt the drains that they may rather have the *Juncus* and *carices* the former inhabitants.*

Little can now be said of the wild animals of Ettrick Forest. It is likely that in ancient times the Urus had been common, for skulls of that animal have frequently been found in the marl mosses along with those of the stag,† and another extinct species of deer with palmated antlers, of a size which seem to indicate the bearers to have been as large as a blood horse.‡ The wolf and the wild boar had been common, for several places bear their names to this day. Foxes in the memory of old people were very destructive, but now few of them even attack lambs. The wild cat is nearly if not altogether extinct.

Two species of mice have occasionally been met with, which as yet have been overlooked by scientific naturalists. One inhabits the tops of the highest mountains, is a little larger than the *Mus sylvaticus*. The fur has a silky softness and lustre, and as the animal is turned round it falls open by its weight in a shed along the body, being apparently attached to the skin by a filament of extraordinary fineness and elasticity. The other is of a size between this and the *Mus aquaticus*, has, like them, a short tail and ears; the tail tipped with white. It has very large strong grooved semicircular teeth, and inhabits the low grounds, but is extremely rare. Only three have been observed, one of which, when running, stopped at times and stood upright with its fore paws over its eyes like a weasel or squirrel. It was known and distinguished by a mole catcher, who had sometimes, although rarely, caught it in his traps. Rabbits seem to have gradually ascended the rivers, and in the lower part of the county have increased so much as to have become a nuisance.

Birds, migratory and resident, are similar to those of the adjoining districts. The black grouse was not uncommon seventy or eighty years ago, but from some unknown cause left this part of the country, but were again introduced as well as pheasants by the late Duke of Buccleugh, both of which have become uncommonly numerous. Partridges and hares are plentiful, and red grouse or *muirfowl* remarkably so on the heathy grounds. The green and grey plover are likewise common, but not so the woodcock. The dotterel sometimes breeds on the higher mountains adjoining Peeblesshire. There is hardly such a variety of small birds as in the neighbouring counties.

Salmon, grils, whitling, many subspecies of trout, lampreys, eels, pike, minows, barbels, sticklebacks, are found in the rivers, but far from so numerous as formerly: and pike, perch, eels, and some excellent varieties of trout inhabit the lochs.

In ancient times, the sheriffdom of Selkirk was known by the general name of The Forest, or sometimes Ettrick Forest, although in the oldest deeds relating to it, it appears to have been divided into Selkirk Forest, Ettrick Forest, and the Forest of Traquaire or Strathquaire, and is so designated by Robert I. when he made a grant of the lands to the famous Sir James Douglas. Upon the attainture of the family of Douglas in 1455, these forests were again annexed to the crown, in the immediate possession of which and of its tenants they remained until alienated by royal charter after the restoration. We find that upon the 24th May 1503, James IV. granted the forest of Ettrick and the town of Newark as dower to his queen Margaret of England. In 1529, we find from Leslie that James V. had 10,000 sheep "going in the Ettrick Forest, in keeping by Andrew Bell, who made the king so good count of them as they had gone in the bounds of Fife."

In consequence of the whole county being anciently the property of the king, or of the Abbey of Melrose, the proprietors hold their lands by charter from the crown. Two-thirds belong to the Duke of Buccleugh, the rest is divided among twenty-seven other freeholders. The valued rent is £80,307, 15s. 6d. Scottish money; and in 1812, the real rent was £41,160, 10s. sterling. The land rent was then divided among forty-four estates, nine of which were above £2000 Scots, twenty between £2000 and £500, and fifteen below £500. About two-fifths of the county is under entail.

The office of sheriff was hereditary in the ancient

* The following are the principal plants that contribute to support the sheep after the failure of their winter pasture. They are stated in succession. *Festura ovina*, which continues to spring through winter in open weather. *Nardus stricta*, the roots of *C. palustris*, *Dactylis glomerata*, *Eriophorum vaginatum*, a variety of *J. agrestis*, *J. articulatus*, *Anthoxanthum odoratum* and *Poa trivialis*, below the drains on the mossy bogs, and in some high grounds large tracts entirely filled with *Scirpus cespitosa*, which are set on fire annually. This is done when the sun shines and the withered plants are dry and brittle, and the flame streams along the ground in a rapid and beautiful manner. The points of the young sprouts rise through the black surface like the braird of corn, and during or after a shower, are cropt with great avidity by the spreading flocks.

† In early times Ettrick Forest was celebrated for its red deer, and were accounted the largest and finest in the kingdom.

‡ Probably the same as the deer of Saomme of Cuvier.

family of Murray of Philliphaugh. Sir Walter Scott was deputed to that office in 1801.

The principal towns in Selkirkshire are Selkirk, already described, and Galashiels, one half of which nearly is in Roxburghshire. Galashiels is situated on the south bank of the river Gala, with the exception of a part of it called Buckholm side, which stands on the north bank, and is in Roxburghshire. It is a neat thriving town, and contains many good and substantial houses, most of which are covered with slate. A new street, containing many handsome houses, has been just finished (1828,) facing the Gala. The Gala is here crossed by two bridges, one of stone, and the other a private suspension one of iron wire, which was the first that was erected in Britain. The merit of the construction is due to Mr. Richard Lees, an extensive woollen manufacturer, whose works are situated on both sides of the Gala, and who conceived the idea of constructing a foot bridge to form a communication between them. It was accordingly erected in November 1816. The length is 111 feet, and it cost £40. Galashiels has been long celebrated for its woollen manufactures, which being at first very coarse, and of a grey colour, were known throughout Scotland by the name of "Galashiels Grey." Broad cloths, however, of every degree of fineness have been for some years manufactured in the town. A considerable quantity of the wool produced in the country is manufactured at Galashiels. Water power is employed. The parish church of Galashiels is a neat modern building. There is also a Relief meeting house in the town.

There are very few objects of antiquity in this county. In the eastern part of it there are the remains of seven British stations, erected upon heights, and having a slightly elliptical form; and in the midst of several of these there is a Roman camp in the parish of Roberton. One of the most remarkable remains of the Britons is the battle fence or "Catrail," which consists of a large fence with a rampart on both sides. It is about 28 miles long, and its construction can only be referred to the Romanised Britons, who, after the departure of the Romans, were obliged to defend the country from the invasion of the Saxons on the east during the fifth century. Some of the ruined castles and moss grown towers, erected some of them in the 12th century, are not of sufficient interest to merit description.

The population seems to have increased since Dr. Webster's return in 1755, as follows:

1755	.	4622
1793	.	4646*
1811	.	6143
1821	.	6637

SELTZER Water. See Mineral Waters.

SEMAYLA, a gold mine in Bambouk, is a small hill about 200 feet high, and 5000 in circuit. The gold occurs in a reddish sandstone, and also in a solid bed of red marble. Though the richest mine, therefore, in Bambouk, it is of secondary value. See Bambouk.

SEMENDRIA, the name of a town and fortress of European Turkey, in Servia. It stands on the south side of the Danube, and is defended by an old castle. It was once the residence of the kings of Servia. Population 9000; east longitude, 20°, 41′, north latitude, 44°, 52′.

SEMIRAMIS. See Assyria.

SEMLIN, a town of Sclavonia, near the confluence of the Save and the Danube. It is the seat of the transit trade between Turkey and Sclavonia. The archbishop of the Greek church resides here, and the Austrian commander of the frontier military district. Population 8000.

SENECA, Lucius Annæus, a celebrated ancient philosopher, was born at Corduba in Spain, about the beginning of the Christian era. He was educated at Rome, and his father, who was himself eminent as an orator, instructed him in the study of eloquence. The study of philosophy, however, soon engrossed all his attention, and though he at first joined the Pythagorean sect, yet he afterwards connected himself more closely with the Stoics. He had acquired considerable reputation at the bar, but it is said that he relinquished it out of fear of the vengeance of Caligula, who was himself ambitious of rhetorical fame. Having obtained the office of questor, and risen to distinction in the court of Claudius, he was accused by Messalina of an adulterous connection with Julia, the daughter of Germanicus, and was sent to Corsica, where he spent eight years in exile. All the philosophy which he had acquired could not inspire him with resignation and patience, and he is said to have complained of his lot, and even to have made abject application to the Emperor for pardon.

When Claudius married his second wife Agrippina, Seneca was, at her request, recalled from banishment, and after being elevated to the prætorship, he was appointed tutor to her son Nero. As the account of his political life has been already given under our article Roman Empire, we have only to add that, being commanded by Nero to put an end to his existence, he expired, by opening his veins, in the year 65. His wife, Paulina, had refused every consolation, and had resolved to die the same death with her husband; she had even opened her veins; but the Emperor would not allow her this comfort, and she never recovered from the loss of blood which she had suffered before the arrival of the imperial prohibition.

From the great munificence of Nero, Seneca acquired prodigious wealth. He possessed innumerable villas. His house and garden were the most splendid in Rome, and he had money laid out at interest in every part of the world. If we believe Dio, he had no less than £250,000 sterling at interest in Britain, and the calling in of this sum is said to have been one of the causes of a war with that nation. In the midst of all this wealth, however, Seneca led an abstemious and quiet life.

The philosophical works of Seneca consist of 126 Epistles, and of separate treatises on Consolation, Anger, Providence, Tranquillity of Mind, Constancy, Clemency, the Shortness of Life, a Happy Life, Retirement, and Benefits. His treatise on Consolation was written in Corsica, and was addressed to his mother, Helvia, and his friend Polybius. The tragedies extant under his name, are supposed by some to have

* Dr. Douglas's Survey. It very probable that both Dr. Webster's and Dr. Douglas's returns were much too low.

been written for amusement during his exile, as he himself says, *modo se levioribus studiis ibi oblectasse;* but they are generally supposed not to be his. The 17 Epistles from Seneca to St. Paul are obviously spurious. The last editions of his philosophical works are those of Lipsius, the Variorum, 3 vols. 8vo. the Leipsic, 2 vols. 8vo. and the Bipontine edition. His seven vols. of Natural Questions, included in this edition, contain some curious observations on Egypt and the Nile, which makes it probable that he had travelled in the early part of his life.

SENECA, river of the United States, in New York, is formed by the outlets of Canandaigua, Crooked, Seneca, Cayuga, Owasco, and Skeneatelas lakes. The western and remote source of the Seneca river is Mud creek, rising in the western part of Ontario county, and flowing first north, thence north-east, and finally east, receives the outlet of Canandaigua lake at Lyons, in Wayne county, after a comparative course of 40 miles. At Lyons the stream takes the name of the Clyde, which flowing south-east by east 18 miles joins a much more considerable stream, the outlet of Crooked, Seneca, and Cayuga lakes, and assumes below the junction the name of Seneca river. Turning to a course nearly north one mile, the Seneca is crossed by the Erie canal, and one mile still lower passes the flourishing village of Montezuma, and continuing north four miles winds to the east eleven miles, receiving in the latter course the outlets of Owasco and Skeneatalas lakes. Now a considerable stream, the Seneca, turns NE. by E., and with a very winding bed joins the Oneida, and loses its name after a comparative course of about 100 miles from the source of Mud Creek.

The Seneca river gains importance from its valley being traversed 65 miles by the Erie canal, and from being the drain of the lake region of the western part of New York. The valley of the Seneca is, perhaps, as a body of productive soil unsurpassed, and embracing about 3600 square miles, sweeps over great part of the counties of Ontario, Wayne, Yates, Tomkins, Seneca, Cayuga, Courtland and Onondago counties. This region contains the saline tract of Onondago, though otherwise not very productive in minerals, though gypsum has been discovered. Geographically it extends from N. lat. 42° 15' to 43° 12', and is traversed between the Crooked and Seneca lakes by the meridian of Washington City. In regard to climate the Seneca valley is remarkable as sloping from south to north. The surface of Crooked lake is a small fraction above 700 feet, whilst the junction of the Seneca and Oneida rivers rises only about 200 above the ocean level. The country drained by the sources of Crooked, Seneca, and Cayuga lakes is elevated upwards of one thousand feet above the tide level in Hudson, consequently the higher and lower extremes of the Seneca valley differ in temperature above two degrees of Fahrenheit from mere relative height, and gives a more rigorous climate to the southern than to the northern border. See next Article.

SENECA, lake of the United States in New York, extending in a direction of nearly north and south, from N. lat. 42° 23' to 42° 54', and nearly on the meridian of Washington City. It is 36 miles long, and from 1½ to 2½ miles wide, with depth sufficient for the navigation of large vessels. The sources of this lake are some small creeks of Yates, Steuben, and Tioga counties of New York, rising on a comparatively elevated table land and rushing from ledge to ledge soon falls to the level of the lake, 445 feet above that of the ocean. The waters of Seneca are discharged from its north-east angle, and in a course of 12 miles and fall of 124 feet reaches the level and are lost in the northern extremity of Cayuga lake.

The country adjacent to both these lakes, and indeed the whole surface composing the southern part of the Seneca valley, exhibit a series of high, boldly swelling though seldom precipitous hills, extending from SE. by S. to NW. by N., nearly parallel to the lakes. The intervening valleys are evidently mere continuations of those of the lakes themselves, giving to that section of New York a very peculiar physiognomy. From the head of Seneca lake at the mouth of Catherine creek, to Newtown on the Chemung branch of Susquehannah, is in a direct line 20 miles, and though the circumjacent hills rise to upwards of one thousand, the summit level between the points is only 885 feet above the oceanic level. A canal of practicable execution, has been projected to unite the Seneca lake to the Chemung river by the designated route.

Politically, Seneca lake touches Tioga county south; has Tomkins and the southern part of Seneca county along its eastern, and Steuben, Yates, and the south-eastern part of Ontario along the western border. The fine picturesque village of Geneva, traversed by the meridian of Washington City, stands on the north-west angle of Seneca lake, and is one of the very few borrowed names of places in the United States which has an appropriate local application.

SENECA, county of New York, bounded N. by Wayne county, NE. by Seneca river, E. by Cayuga lake, S. by Tomkins county, W. by Seneca lake, and NW. by Ontario county. Length 32, and varying in width from 6 to 12 miles; area about 300 square miles. The southern part high and hilly, between the Seneca and Cayuga lakes; northern traversed by the Clyde branch of Seneca river, comparatively level. Soil fertile, and in its natural state covered by a dense forest. Chief villages Ovid and Waterloo; the former in the southern part, and latter on the outlet of Seneca lake.

Central lat. 42° 50' N. Central long. 10' E. from Washington City. The principal waters of this county have been given in the delineation of its boundaries, and it may suffice to observe, that from its limited breadth and having the two fine lakes of Seneca and Cayuga as its eastern and western limits, traversed by the outlet of the former, and on its north-eastern angle by the Erie canal, that Seneca county of New York is one of the most navigable inland counties of the United States.

SENECA, county of Ohio, on both sides of Sandusky river, having Sandusky county N., Wood NW., Hancock SW., Crawford S., and Huron E. Length from west to east 30, breadth 18 miles, and area 540 square miles. Chief village or seat of justice Tiffin. Central lat. 41° 08' N. Long. W. from Washington City 6° 12'. Face of the country level or gently waving, soil fertile. In great part unsettled. DARBY.

SENEGA. See MATERIA MEDICA.

SENEGAL, the name of a large river of Africa, already briefly described in our article PHYSICAL GEOGRAPHY. The early part of its course, and of its tributaries, is through a rugged country, intersected by numerous rivers and streams, whose sands contain much gold dust, which is extracted by the women by the process of agitation. For a distance of about 60 leagues from its mouth, below Podor, its descent is said not to exceed two and a half feet. It is here bordered by vast woods, the residence of monkeys and parrots of all kinds. The entrance of the river is defended by a formidable bar of sand, a little under water. Before it throws itself into the sea, it forms the Isle of Senegal in St. Louis, about 1000 paces long, and 60 broad. The eastern branch of the river is here about 800 yards across, and the western one from 100 to 400 yards.

SENEGAL, GOVERNMENT OF, is the name given by the French to their settlement on the island, at the mouth of the above river. This settlement was founded in 1637, under Louis XIV. and the fort thus received the name of Fort Louis. Although the island is merely a mass of white and burning sand, constantly in motion, yet its security from attack recommended it as the site of the colony. The streets, which are regular, consist of huts or thatched cottages, among which are some flat roofed houses of stone. As the island is perfectly barren, it is supplied with every thing from the continent.

In 1787, the white inhabitants amounted to about 60, and the military to about 600. The free Mulatto and Negro population was estimated at 2400, and the domestic and labouring slaves at 2400. These, with 1200 negroes always ready for embarkation to the West Indies, constituted a population of about 6000.

As gum Senegal has been found superior to all other gums, it is one of the principal objects of commerce at Fort Louis. The forests of Acacia, from which this gum exudes, are called Sahel, Al Fatack, and El Hiebar, the first producing the white gum, which is the most esteemed, and the other two the red gum. The trees are about 18 or 20 feet high, and three feet round. The gum begins to exude about the 10th of November, when the periodical rains are over. No incision is needed, but the gum flows from the cracks in the bark, and generally in drops about the size of a partridge's egg. These drops are always transparent and brilliant at the part where they are broken off; and when they have been in the mouth a few seconds, they have all the limpidity of pure quartz.

Early in December the Moors leave their habitations in the desert to the care of old men, and a few servants to tend the cattle, and set out in a tumultuous cavalcade of horsemen, camel drivers, and pedestrians. They then encamp on the borders of the gum forest, and, during a harvest of about six weeks, they fill their leathern sacks with the gum.

The great gum fair is held on a desolate plain of white and moving sands on the north bank of the Senegal, between Podor and St. Louis. The French merchants repair thither to wait the arrival of the Moors. On the morning of the fair a confused and distant noise is first heard, and about noon the whole plain is covered with an army of men, camels, oxen, and goats, surrounded with clouds of dust, with all their baggage, wives, and children. The kings are mounted on fine horses, and their wives are carried on a few chosen camels, highly caparisoned. A band of Moors, equipped with muskets and lances, escort this moving kingdom. When the tumult of the assemblage has subsided, and their camps fairly pitched, a cannon is fired as a signal for the commencement of the fair. Lies and threats of all kinds are employed by the Moors to obtain a high price for their gum, for which they receive in exchange East India cotton goods called pieces of Guinea. Between 1785 and 1787 the French obtained 800,000lbs. of gum exclusive of 400,000 carried to Portendick, and sold to the English. It is sold in kantars of about 500 lbs. and costs about two-pence per pound.

In 1786, there were exported from Senegal cloves valued at 2,640,000 livres, gold valued at 90,000 livres, and ivory and miscellaneous articles valued at 130,000 livres.

In 1756 this colony was taken by Britain, and was afterwards ceded to us in 1763. The French, however, retook it in 1779, and were allowed to retain it till the peace of 1783. They again lost it during the revolutionary war, but it was ceded to them at the restoration of the Bourbons.

SENNA. See MATERIA MEDICA.

SENNAAR, one of the divisions of Nubia in eastern Africa, is bounded by Abyssinia on the east and south, on the west by Darfur, and on the north by Dongola and the independent districts of Nubia. The part of Sennaar between the Nile and the river Tacazze formed what was called by the ancients the Island of Meroe.

The kingdom of Sennaar was founded in 1504 by a body of Shillock negroes. It has three principal governments tributary to it, viz. El-aice or Alleis, Kordofur, and Fazuclo.

El-aice, including the original country of the Shillock Negroes. The Bahr-el-abiad spreads itself over the territory, and by a great number of small channels it forms numerous little islands, on each of which is a village, the union of which constitutes the town of El-aice. The inhabitants, being all fishermen, possess a number of boats like canoes, in which they sail up and down to the cataracts. It was by means of these boats that the Shillock Negroes succeeded in conquering the Arabs in 1504.

Kordofan is next in importance to El-aice. The revenue consists chiefly in the slaves which are procured from Dyre and Tegla. Being nearest to Darfur, it has often been taken from Sennaar and retaken.

Fazuclo is bounded on the west by the river El-aice, and on the east by the Nile, and on the south by the mountains of Fazuclo, where the great cataracts are. The greater part of the revenue of Fazuclo is derived from gold obtained from the mountains.

The territory of Sennaar is remarkably fertile to a considerable distance from the banks of the river. In the rainy season, about the end of August, the appearance is delightful, the corn springs up, and the whole country appears a level green park, interspersed with lakes, and decorated with groups of villages. Through this immense plain flows the Nile, above a mile broad and full to the very brim. Upon the cessation of the rains the Dhourra ripens, the lakes become putrid and full of vermin, and poisonous winds, and burning sands, and sultry blasts desolate the plain.

The principal places are Sennaar the capital, and

Halfaia, a large, handsome, and pleasant town, built with clay, in north lat. 15° 45′ 54″, and east by 32° 49′ 15″. The houses are terraced at the top, and are about 300 in number. It stands upon a large circular peninsula, and surrounded by the Nile, which is about half a mile from the town. It derives its principal support from a manufacture of coarse cotton cloths, which serve for small money throughout the lower parts of Atbara. The people eat cats, and also the sea horse and crocodile. Their salt is extracted from the earth. Aira is another place about three or four miles from Sennaar; it is surrounded with white sand which is sown with millet. Shaddly, about twelve miles to the north north west of Sennaar, is a collection of villages; it received its name from a saint, who directed large pits to be dug, and plastered closely up with clay, for the purpose of being filled with grain when it was cheapest. These pits, called *matamores*, were plastered up at top. They occur in great numbers throughout the plain, and when there is any prospect of corn growing dear, they are opened, and the corn sold at a low price. About 24 miles to the north of Shaddly, is another more extensive establishment of the same kind, called Wed-aboud.

To the westward of Shaddly and Aboud, as far as the Abiad or El-aice, the country is covered with trees, which makes it an excellent station for camels. Near Shaddly are two mountain districts, viz. Jibbel-Moia, or the mountains of water, and Jibbel-Segod, or the Gold Mountains; the first is a considerable ridge of hills closely united and of the same height, and the second is a broken ridge, unequal and irregular. They are full of inhabitants, who enjoy a fine climate.

The dress of the people of Sennaar consists of a long shirt of blue cotton cloth, which reaches to the feet, and the only difference between that of the men and women is, that the men have the neck left bare, while the others have a shirt neck, which is buttoned like ours. Both men and women go barefooted in the house. They anoint themselves, at least once a day, with camels' grease, mixed with civet, and they sleep all night upon a bull's hide, and in a shirt dipped in grease.

Bread of flour or millet, is the diet of the poorer sort. The horned cattle are the largest and finest in the world, and are very fine, but camels' flesh is the common meat sold in the market. The liver of the camel, and the spare rib are universally eaten raw. Hogs' flesh, though not sold in the market, is publicly eaten.

Dysenteries, intermittent fever, epileptic and scirrhous livers are the principal diseases. The small pox is sometimes 12 or 15 years absent. They have a process of inoculation called *buying the small pox*.

The county has very little trade; the principal article of consumption is the blue cotton cloth from Surat. Their commerce consists chiefly in exchanging the productions of the interior of Africa with those of Arabia and Egypt. The articles from Africa are gold dust called Tibber, civet, Rhinoceros' horns, ivory, ostriches' feathers, glass and slaves. The gold is deemed the finest and best in Africa. They receive also spices, hardware, and toys, particularly black beads from Venice.

SENNAAR, a city of Africa, and the capital of the above kingdom, is situated on the banks of the Bahr-el Azrek, a river of Abyssinia, about 200 miles before it falls into the Abiad, or chief branch of the Nile. The houses are poorly built, consisting merely of clay intermixed with a little straw. They are all one story high, except those of the officers of state, which are two stories high. They have flat parapet roofs, though in other parts of the kingdom the roofs are conical to keep off the heavy rains. The palace is encircled with a lofty brick wall, but the buildings which compose it have neither order nor beauty. Splendid carpets are among their principal ornaments. Mr. Bruce has recorded the very singular fact, that neither horses, mules, asses, nor any domestic animal was bred in the town, or in any district several miles round it. Few of these animals can live there all the year round, but must be carried every half year to the sands, distant about four miles. At this place, Adelan, the actual ruler, kept his stud in good condition. A dreadful malady also prevails among the children: and it is said that there is a constant importation of slaves from the south in order to keep up the population. When the river overflows its banks, the houses near its banks are inundated, and are generally destroyed in consequence of the melting of the clay walls. Population about 160,000. The thermometer is said by Bruce to rise sometimes to 119° in the shade. East long. 33° 30′ 30″. North lat. 13° 34′ 36″. See Bruce's *Travels*.

SENS, a town of France, in the department of the Yonne, is agreeably situated on the slope of a hill, and is watered by the Yonne and the Vaune. Before the Revolution it was the see of an archbishop, and contained 16 Parish churches, and 14 abbeys and convents. The cathedral is a very fine piece of architecture, and its interior has been much admired. It contains the tomb of the dauphin, son of Louis XV., and that of Chancellor Dupradt. There is a library and museum belonging to the college. It carries on a trade in wine, corn, wood, coal, and hemp. Population 9000.

SEQUATCHE, small river of the United States in Tennessee, rises in Bledsoe, and flowing thence into Marion, which latter it traverses, and crossing the boundary line between Tennessee and Georgia, enters Tennessee river on the extreme northern border of the latter, after a comparative course of sixty miles. It is a mountain stream, rising and flowing between two lateral ridges of Cumberland mountain. DARBY.

SERAMPORE, a town of Bengal belonging to Denmark. It is agreeably situated on the west bank of the Bhagarutti or Hoogly river. The territory which belongs to it is about a mile long and half a mile broad, stretching along the banks of the river. The houses are seldom above two stories high, and are built of brick, and plastered with mortar. They have balconies, Venetian windows, and flat roofs. A handsome church is the principal public building. The town is not fortified; but there is near the flagstaff a battery of 12 pieces of cannon. A very trifling trade is carried on between this place and China and Europe. Being a sanctuary for creditors, which are British subjects, it is principally supported by them and by the missionaries. East long. 88° 26′. North lat. 22° 45′.

SERIES.

Series, in *Analysis*, is a number of quantities arranged in a certain order or succession, and so related that each succeeding quantity may be known from those which precede it.

The quantities which compose a *series* are called its *terms*, and that relation which is observable among the *terms* by which they may be successively determined, is called the *law of the series*.

Series are denominated, according to the nature of their terms, *numerical* or *algebraical*. Thus

$$1, \quad 2, \quad 3, \quad 4, \text{ \&c.}$$
$$1, \quad \frac{1}{2}, \quad \frac{1}{3}, \quad \frac{1}{4}, \text{ \&c.}$$

are numerical series, and

$$x, \quad x^2, \quad x^3, \quad x^4, \text{ \&c.}$$
$$\frac{1}{a}, \quad \frac{b}{a^2}, \quad \frac{b^2}{a^3}, \quad \frac{b^3}{a^4}, \text{ \&c.}$$

are algebraical series.

The *laws* of these series are severally obvious upon inspection, and there is no difficulty in continuing them to any number of terms.

Series are variously denominated in reference to their *laws*.

An *arithmetical series* is one in which each term is found by adding to or subtracting from the preceding term the same quantity. Such are the following:

$$1, \quad 2, \quad 3, \quad 4, \text{ \&c.}$$
$$3, \quad 6, \quad 9, \quad 12, \text{ \&c.}$$
$$a, a+d, \; a+2\,d, \; a+3\,d, \text{ \&c.}$$
$$a, a-d, \; a-2\,d, \; a-3\,d, \text{ \&c.}$$

A *geometrical series* is one in which each term is found by multiplying the preceding term by the same quantity. Such are the following:

$$2, \quad 4, \quad 8, \quad 16, \text{ \&c.}$$
$$a, \quad ax, \quad ax^2, \quad ax^3, \text{ \&c.}$$

2 being the multiplier in the former, and x in the latter.

An *harmonical series* is one in which the reciprocal of each term is found by adding to or subtracting from the reciprocal of the preceding term the same quantity. Such are

$$1, \quad \frac{1}{2}, \quad \frac{1}{3}, \quad \frac{1}{4}, \text{ \&c.}$$

$$\frac{b}{a}, \quad \frac{b}{a+d}, \quad \frac{b}{a+2d}, \quad \frac{a}{a+3d}, \text{ \&c.}$$

the quantity added being 1 in the former, and $\frac{d}{b}$ in the latter.

These three series are commonly called *progressions*. For a detailed account of their properties, see Algebra.

A *recurring series* is a general class, of which a geometrical series is a particular example. As each term of a geometrical series is produced by multiplying the preceding term by a constant quantity, so in a recurring series each term is found by multiplying a certain number of the terms which immediately precede it by as many constant quantities. Thus let A and B be any two successive terms of a recurring series, and let a and b be the constant multipliers, the next term will be $a\,A + b\,B$. Let this be called C, that is, let $a\,A + b\,B = C$; then the succeeding term is $a\,B + b\,C$. Again, let $a\,B + b\,C = D$, and the following term is $a\,C + b\,D$, and so on.

In like manner, if the series be produced by three constant multipliers, each term may be found from the three terms which immediately precede it. Let A, B, and C, be the three consecutive terms, a, b, c, the three constant multipliers, and let D, E, F, &c. be the terms which immediately succeed C. Then we have

$$\begin{aligned} D &= a\,A + b\,B + c\,C \\ E &= a\,B + b\,C + c\,D \\ F &= a\,C + b\,D + c\,E \\ &- \quad - \quad - \quad - \\ &- \quad - \quad - \quad - \end{aligned}$$

and the process would be similar if the series were generated by four or more constant multipliers.

In a recurring series the system of constant multipliers is called the *scale of relation*, and the series is said to be *a recurring series of the first, second, third, or mth order*, according as the number of constant multipliers in the scale of relation is 1, 2, 3, or m.

It is evident that a recurring series of the first order is a geometrical series.

When powers of the same letter or species enter all the terms of a series as factors, the series is called an *ascending* or *descending* series with respect to this quantity, according as the exponents of the power increase or decrease. Thus the following is an ascending series with respect to x, and a descending one with respect to a.

$$a^m, \; a^{m-1}\,x, \; a^{m-2}\,x^2, \; a^{m-3}\,x^3, \text{ \&c.}$$

The *general term* of a series is an algebraical formula, which is usually a function of the quantities which are engaged in the series, and a general symbol n, denoting the place of any term or its numerical order relatively to some term which is considered as the first term of the series, or the point of departure to which the places of all the other terms are referred. Thus in the last example, if a^m be considered as the first term, it appears that the number which is subtracted from m in the exponent of a in each term is equal to the number of preceding terms, and therefore is one less than the number which denotes the place of the term itself; and the exponent of x in each term is the number which is subtracted from m in the exponent of a in the same term. Thus if n denote the numerical order of any term T, we have

$$T = a^{m-(n-1)}\,x^{n-1}.$$

It is obvious that the formula which expresses the general term of a series also expresses its *law*, and that the terms of the series may be found by substituting the successive integers 1, 2, 3, &c. for n in this formula.

The terms of a series are generally connected together by the algebraical signs + or —, and it is to the whole thus connected that the term *series* is applied.

A series generally arises from some analytical process to which a function or formula has been submitted, and this process is called *development;* the finite *formula* is said to be *developed*, and the resulting series is called its *development.*

There are several methods of development adapted to the various forms which fractions may assume. The principal and the most general of these are the *method of indeterminate coefficients* and *the theorem of Lagrange.* Under the latter is comprehended several methods which are sometimes enumerated separately; such as, the method of division, the binomial theorem, Taylor's theorem, Maclaurin's theorem, &c. These methods the reader will find explained in the articles ALGEBRA and FLUXIONS. Numerous applications of these processes will also be found in several of our mathematical articles, as, TRIGONOMETRY, LOGARITHMS, &c.

The *summation* of a series is that process by which the algebraical sum of any number of its terms, or even of the whole series continued *ad infinitum*, may be found.

The summation of series is a subject which has engaged the attention of the most eminent modern analysts, from the time of Wallis, who seems first to have given the doctrine of series that consideration which its importance demands, to the present day. Any detailed account of these various methods of summation, which have been proposed by modern mathematicians, would exceed those limits which we find it expedient to impose on such a discussion in this work. We shall therefore confine ourselves to a few examples, illustrative of some of the principal methods.

To determine the sum of a series of fractions, whose numerators are in arithmetical, and whose denominators are in geometrical progression: the number of terms being supposed infinite.

Let the series be expressed thus,

$$\frac{a}{a'}+\frac{a+d}{a'r}+\frac{a+2d}{a'r^2}+\frac{a+3d}{a'r^3}+\cdots \quad [1]$$

By the formulæ established in article ALGEBRA, for summing a decreasing geometrical series continued *in infinitum*, we have the following results:

$$\frac{a}{a'}+\frac{a}{a'r}+\frac{a}{a'r^2}+\frac{a}{a'r^3}+\cdots=\frac{ar}{a'r-a'}$$
$$\frac{d}{a'r}+\frac{d}{a'r^2}+\frac{d}{a'r^3}+\cdots=\frac{d}{a'r-a'}$$
$$\frac{d}{a'r^2}+\frac{d}{a'r^3}+\cdots=\frac{d}{a'r^2-a'r}$$
$$\frac{d}{a'r^3}+\cdots=\frac{d}{a'r^3-a'r^2}$$
$$+\cdots=\cdots$$
$$\cdots=\cdots$$

It is evident that the proposed series is the sum of the first members of these equations. If then we express this sum by S, we have

$$S=\frac{ar}{a'(r-1)}+\frac{d}{a'(r-1)}\left\{1+\frac{1}{r}+\frac{1}{r^2}+\frac{1}{r^3}+\cdots\right\}$$

The series within the brackets, in the second member of this equation, is also a geometrical series in which $\frac{1}{r}$ is the constant multiplier. Its sum continued *in infinitum*, therefore $\frac{r}{r-1}$. Hence we obtain

$$S=\frac{ar}{a'(r-1)}+\frac{dr}{a'(r-1)^2}$$
$$\text{or } S=\frac{ar(r-1)+dr}{a'(r-1)^2}$$

The same method of summation may be applied to the case in which the numerators, instead of being in arithmetical progression, are composed of a constant quantity a, connected by addition, with terms composed of a constant factor d, and the triangular numbers 1, 3, 6, 10, &c. Thus let the series be,

$$S=\frac{a}{a'}+\frac{a+d}{a'r}+\frac{a+3d}{a'r^2}+\frac{a+6d}{a'r^3}+\cdots$$

As before we obtain the following equations by the summation of geometrical series:

$$\frac{a}{a'}+\frac{a}{a'r}+\frac{a}{a'r^2}+\frac{a}{a'r^3}+\frac{a}{a'r^4}+\cdots=\frac{ar}{a'r-a'}$$
$$\frac{d}{a'r}+\frac{d}{a'r^2}+\frac{d}{a'r^3}+\frac{d}{a'r^4}+\cdots=\frac{d}{a'r-a'}$$
$$\frac{2d}{a'r^2}+\frac{2d}{a'r^3}+\frac{2d}{a'r^4}+\cdots=\frac{2d}{a'r^2-a'r}$$
$$\frac{3d}{a'r^3}+\frac{3d}{a'r^4}+\cdots=\frac{3d}{a'r^3-a'r^2}$$
$$\frac{4d}{a'r^4}+\cdots=\frac{4d}{a'r^4-a'r^3}$$
$$+\cdots=\cdots$$
$$\cdots=\cdots$$

As before the sum of the first members is S; so that we have

$$S=\frac{ar}{a'(r-1)}+\frac{d}{a'(r-1)}\left\{1+\frac{2}{r}+\frac{3}{r^2}+\frac{4}{r^3}+\cdots\right\}$$

In the series which is within the brackets, the numerators are in arithmetical progression, and therefore its sum may be obtained by the general formula established in the preceding example. This will be effected by making $a=a'=d=1$, whence we obtain

$$1+\frac{2}{r}+\frac{3}{r^2}+\frac{4}{r^3}+\cdots=\frac{r^2}{(r-1)^2}$$

Hence we find

$$S=\frac{ar}{a'(r-1)}+\frac{dr^2}{a'(r-1)^3}$$

By dividing the former series by r, we have

$$\frac{1}{r}+\frac{2}{r^2}+\frac{3}{r^3}+\frac{4}{r^4}+\cdots=\frac{r}{(r-1)^2}$$

Hence

$$\frac{1}{2}+\frac{2}{2^2}+\frac{3}{2^3}+\frac{4}{2^4}+\cdots=2$$
$$\frac{1}{3}+\frac{2}{3^2}+\frac{3}{3^3}+\frac{4}{3^4}+\cdots=\frac{3}{4}$$

and so on.

If in the series (2), we make $a=0$, $a'=1$ and $d=1$ we obtain,

$$\frac{1}{r}+\frac{3}{r^2}+\frac{6}{r^3}+\frac{10}{r^4}+\cdots=\frac{r^2}{(r-1)^3}$$

Hence we find

$$\frac{1}{2}+\frac{3}{2^2}+\frac{6}{2^3}+\frac{10}{2^4}+\cdots=4$$
$$\frac{1}{3}+\frac{3}{3^2}+\frac{6}{3^3}+\frac{10}{3^4}+\cdots=\frac{9}{8}$$

and so on.

This method of *summation by addition* was proposed by James Bernoulli, in a tract *De Seriebus Infinitis*, published with his *Ars Conjectandi*. Bas. 1713.

Another method of summation suggested by the *Bernoullis* on the same principle, is *summation by subtraction*, of which the following is an example.

To find the sum of an infinite series of reciprocal triangular numbers. Let the series be

$$S = \frac{1}{1} + \frac{1}{3} + \frac{1}{6} + \frac{1}{10} + \cdots$$

Divide both members by 2, and we obtain

$$\frac{S}{2} = \frac{1}{2} + \frac{1}{6} + \frac{1}{12} + \frac{1}{20} + \cdots$$

$$= \frac{1}{1\cdot 2} + \frac{1}{2\cdot 3} + \frac{1}{3\cdot 4} + \frac{1}{4\cdot 5} + \cdots$$

$$= \left(1 - \frac{1}{2}\right) + \left(\frac{1}{2} - \frac{1}{3}\right) + \left(\frac{1}{3} - \frac{1}{4}\right) + \cdots$$

$$\therefore \frac{S}{2} = \left\{1 + \tfrac{1}{2} + \tfrac{1}{3} + \tfrac{1}{4} +, \&c.\right\} - \left\{\tfrac{1}{2} + \tfrac{1}{3} + \tfrac{1}{4} +, \&c.\right\}$$

$$\therefore \frac{S}{2} = 1 \qquad \therefore S = 2$$

In the preceding examples, we have applied these methods of addition and subtraction only to cases in which the series were continued *in infinitum*. We can, however, frequently employ them for the summation of a finite number of terms of a series. Numerous instances of this occur in trigonometry. The following are examples of it.

Ex. *To find the sum of the sines of a series of arcs in arithmetical progression.*

Let the proposed series be

$$\text{Sin } A + \sin(A + x) + \sin(A + 2x) + \cdots \text{Sin}[A + (n-1)x] = S. \quad [1]$$

Let both members be multiplied by $-2\sin\frac{1}{2}x$. Hence

$$-2\sin\tfrac{1}{2}x\sin A - 2\sin\tfrac{1}{2}x\sin(A+x) - \sin\tfrac{1}{2}x\sin(A+2x) - \cdots - 2\sin\tfrac{1}{2}x(\sin[A+(n-1)x] = -2\sin\tfrac{1}{2}x\cdot S.$$

Every term of this series is of the form $-2\sin\frac{1}{2}x\sin(A + mx)$,

and by the principles of trigonometry, we have

$$-2\sin\tfrac{1}{2}x\sin(A + mx) = \cos\left(A + \frac{2m+1}{2}x\right) - \cos\left(A + \frac{2m-1}{2}x\right).$$

by substituting successively 0, 1, 2, 3, --- $(n-1)$, for m in this formula we shall obtain the values of the successive terms of the above series, and it is plain that except the first and last they will mutually destroy each other; so that the result will be

$$-\cos(A - \tfrac{1}{2}x) + \cos\left(A + \frac{2n+1}{2}x\right) = -2\sin\tfrac{1}{2}x$$

$$\therefore S\sin\tfrac{1}{2}x = \sin\left(A + \frac{n-1}{2}x\right)\sin\frac{n}{2}x$$

$$\therefore S = \frac{\sin\left(A + \frac{n-1}{2}x\right)\sin\frac{n}{2}x}{\sin\frac{1}{2}x},$$

which is the sum required.

If $A = x$, the series becomes

$$\sin x + \sin 2x + \sin 3x \cdots + \sin nx = S,$$

and we have

$$S = \frac{\sin\frac{n+1}{2}x\sin\frac{n}{2}x}{\sin\frac{1}{2}x}.$$

It will be perceived that the artifice by which the summation of this series has been brought under the methods of addition and subtraction, is by converting it into another series, every term of which being double the product of two sines, admits of being resolved into two simple cosines, with different signs. In this case, one of the cosines into which each term is resolved, destroys one of the cosines into which the next term is resolved; so that however numerous the terms of the series may be, the total result can only contain one of the cosines of the first pair, and one of the last pair. If the last cosine continually diminished or approached any value as a limit, as the number of terms in the series increases, we should be entitled to conclude that the sum of the proposed series continued *ad infinitum*, would be expressed by the first cosine and the limiting value of the last. If we assume that the sum of the series is expressed by the first term alone, it is equivalent to assuming that the last term diminishes without limit.

This, however, is not the case; the last cosine alternately increases and diminishes, and changes its sign as the arc changes its relation to an exact multiple of the circumference; and therefore the series increases and decreases alternately, and approaches no limiting state. In other words, the series not being convergent, does not admit of having its sum assigned when the number of its terms are limited.

If x be commensurable with the circumference, or 2π, the series will be *periodic*: that is, after a certain number of terms, the same terms will continually recur in the same order. Let the least integers in the ratio of x to 2π be $m' : n'$; so that

$$n'x = 2m'\pi.$$

In that case, when the series [1] has been continued to n' terms, the $(n'+1)^{\text{th}}$, term will be

$$\text{Sin}(A + 2m'x, = \sin(A + 2m'\pi) = \sin A.$$

In like manner, the following term will be

$$\text{Sin}[A + (n'+1)x] = \sin(A + x + 2m'\pi) = \sin(A + x,)$$

which is equal to the second term of the series, and so the terms from the $(n'+1)^{\text{th}}$ to the $2n'^{\text{th}}$ inclusive, will be equal to those from the first to the n'^{th} inclusive.

In this case, the value of the period of the series may be found by substituting $\frac{2m'\pi}{n'}$ for x, and n' for n in the value of S, already found; which gives

$$S = \frac{\text{Sin}\left(A + \frac{(n'-1)m'\pi}{n'}\right)\sin m'\pi}{\text{Sin}\frac{m'\pi}{n'}}.$$

If $\frac{m'}{n'}$ be not an integer, the value of S must $= 0$, for $\sin m'\pi = 0$, and $\sin\frac{m'\pi}{n'}$ cannot $= 0$. Therefore, in this case, the terms of the period mutually destroy each other, or the whole period might be divided into two periods, the terms of which differ only in their signs. But if $\frac{m'}{n'}$ be an integer, then $\sin \frac{m'}{n'} \pi = 0$; and the value of S assumes the form $\frac{0}{0}$. In this case x is an exact multiple of the circumference, and the terms of the series are all equal to sin A, which is itself the period.

One meaning of "the sum of a periodic series continued *ad infinitum*," would evidently be the product of the value of the period, and an infinite integer, or the period added to itself *ad inf.* It may, however, be considered, that if continued *ad inf.* every term of the period has as strong a claim as its last term to be considered as the last term of the series. The sum of a periodic series, whose period $= 0$, continued *ad inf.* is therefore susceptible of as many *different* values as there are different terms in its period. If the last term of the series be the first term of the period, that term will be equal to the sum. If the last term of the series be the second term of the period, the sum of the series will be the sum of the first two terms of the period; and if the last term of the series be the third term of the period, the sum of the series will be the sum of the first three terms of the period, and so on. It is, therefore, evident, that the variety of values of which the sum of the series is susceptible, whether continued *ad inf.* or not, is limited by the number of different terms in the period.

Now the sum of the series continued *ad inf.* is sometimes said to be a mean of all its different values, or to be the sum of all the different values divided by their number. We shall give an instance of this in the series of which we have already obtained the sum.

If n' be the number of different terms in the series, we shall obtain the n' different values of the sum by successively substituting 0, 1, 2, - - - - n' for n in the equation.

$$\cos (A - \tfrac{1}{2} x) - \cos \left(A + \frac{2n+1}{2} x\right) = 2 \sin \tfrac{1}{2} x \,.\, S$$

Let S′ be the sum of all the corresponding values of S. Since the sum of all the corresponding values of $\cos (A + \frac{2n+1}{2} x)$, is the period, which by hyp. $= 0$ we have

$$n' \cos (A - \tfrac{1}{2} x) = 2 \sin \tfrac{1}{2} x \,.\, S'$$

$$\therefore \frac{S'}{n'} = \frac{\cos (A - \frac{1}{2} x)}{2 \sin \frac{1}{2} x}$$

This is the value of S which would be obtained by neglecting the last cosine in the investigation already instituted, and it hence appears that we cannot infer that the sum of the series *ad inf.* has this value, except when the series is periodic, and its period $= 0$, and even then the sum of the series has this value only in the sense above explained, which is, that the sum *ad inf.* is susceptible of as many different values as there are terms in the period, and that which is found above is its mean value, or the sum of all its different values divided by their number.

In general, however, the summation of a series continued *ad inf.* is, properly speaking, an analytical process wich is the reverse of *development.* As *development* is the process by which a function expressed in finite terms is converted into a series, so *summation* is that process by which, when a series is given, the function by whose development it was obtained may be assigned. The word *summation* cannot be literally applied to this process, except in the case where the series *converges*, for, except in this case, there cannot be an arithmetical equality between the function and the series. This will very evidently appear by an example. Let 1 be divided by $(1 - a)$ by the ordinary rules of algebraical division, and we obtain

$$\frac{1}{1-a} = 1 + a + a^2 + a^3 + a^4 + \cdots \textit{ad inf.}$$

If a be greater than unity, the second member of this equation is an infinitely great positive quantity, while the first member is a finite negative quantity. In this case no actual equality can subsist, and the sign $=$ only signifies that the first member is the function by whose development the series in the second member is obtained.

The method used in the last examples may sometimes be applied to the summation of a finite number of terms of a numerical series as in the following example.

Let the series be

$$S = \frac{1}{1.3} + \frac{1}{3.5} + \frac{1}{5.7} +$$

continued to n terms.

The nth term will evidently be $\frac{1}{(2n-1)(2n+1)}$

We have

$$1 - \frac{1}{3} = \frac{2}{1.3}$$

$$\frac{1}{3} - \frac{1}{5} = \frac{2}{3.5}$$

$$\frac{1}{5} - \frac{1}{7} = \frac{2}{5.7}$$

$$\cdots\cdot = \cdot\,\cdot$$

$$\cdots\cdot = \cdot\,\cdot$$

$$\frac{1}{2n-1} - \frac{1}{2n+1} = \frac{2}{(2n-1)(2n+1)}$$

The sum of the first members of these equalities is evidently $1 - \frac{1}{2n+1}$ since all the other terms mutually destroy each other, and the sum of the second members is 2 S. Hence we obtain

$$2\,S = 1 - \frac{1}{2n+1} = \frac{2n}{2n+1}$$

$$\therefore S = \frac{n}{2n+1}$$

But by far the most general method for the summation of series is that which is derived from the principles of the calculus of differences, which we shall now briefly explain and illustrate by examples.

If the successive terms of a series be expressed by u_1, u_2, u_3, &c. u_x, the number at the foot of the letter denoting the place of the term, the sum of all the terms from u_1 to u_x inclusive, may be expressed thus, $S\,u_x$. Thus we have

$$S\,u_x = u_1 + u_2 + u_3 + \ldots + u_x.$$

In like manner

$$S\,u_{x+n} = u_1 + u_2 + u_3 + \ldots + u_x + u_{x+1} + \ldots u_{x+n}$$

Subtracting the former from the latter, we have

$$S\,u_{x+n} - S\,u_x = u_{x+1} + u_{x+2} + u_{x+3} + \ldots u_{x+n}$$

by which we may express the sum of any number of terms of a series, commencing and terminating at any proposed terms.

If $n = 1$, we have

$$S\,u_{x+1} - S\,u_x = u_{x+1}$$

But

$$\Delta\,(S\,u_x) = S\,u_{x+1} - S\,u_x$$

$$\therefore \Delta\,(S\,u_x) = u_{x+1}$$

$$\therefore S\,u_x = \Sigma\,u_{x+1} + C$$

C being an arbitrary constant.

When $x = 0$, $S\,u_x = 0 \therefore 0 = \Sigma\,u_1 + C$

subtracting this equation from the last, we have

$$S u_x = \Sigma\,u_{x+1} - \Sigma\,u_1,$$

Hence it appears that the summation of a series depends on the integration of u_{x+1} and u_1 considered as differences.

In like manner, if the sum of the series from the nth to the xth term, including the latter, be required, we have

$$S\,u_x - S\,u_n = u_{n+1} + u_{n+2} + \ldots\, u_x$$

But by what has just been proved

$$S\,u_x = \Sigma\,u_{x+1} - \Sigma\,u_1$$

$$S\,u_n = \Sigma\,u_{n+1} - \Sigma\,u_1$$

$$\therefore S\,u_x - S\,u_n = \Sigma\,u_{x+1} - \Sigma\,u_{n+1}$$

We shall now give some examples of the application of these principles, to the summation of series.

Ex. 1. *To determine the sum of a series of figurate numbers of the first, second, and successive orders, beginning with unity in each series.*

For the figurates of the first order we have

$$S\,u_x = 1 + 2 + 3 + \ldots\, x$$

$$\therefore u_x = x$$

$$\therefore S\,u_x = \Sigma\,(x + 1) + C$$

But by the calculus of differences we have

$$\Sigma\,(x) = \frac{x^2}{2h} - \frac{x}{2}$$

Changing x into $x + 1$, and h into 1, we have

$$\Sigma\,u_{x+1} = \frac{(x+1)^2 - x}{2} + C$$

$$\therefore \Sigma\,u_1 = \frac{1}{2} + C$$

Subtracting this from the former we have

$$\Sigma\,u_{x+1} - \Sigma\,u_1 = \frac{x\,(x+1)}{1\,.\,2}$$

$$\therefore 1 + 2 + 3 \ldots + x = \frac{x\,(x+1)}{1\,.\,2}$$

For the figurates of the second order

$$u_x = \frac{x\,(x+1)}{1\,.\,2} \quad u_{x+1} = \frac{(x+1)\,(x+2)}{1\,.\,2}$$

$$\Sigma\,u_{x+1} = \frac{x\,(x+1)\,(x+2)}{1\,.\,2\,.\,3} + C$$

$$\therefore \Sigma\,u_x = \frac{x\,(x+1)\,(x+2)}{1\,.\,2\,.\,3}$$

no constant being added, because when $x = o$, $S\,u_x = o$.

In general, for the figurates of the nth order we have

$$u_{x+1} = \frac{(x+1)\,(x+2)\,(x+3) \ldots\ldots (x+n)}{1\,.\,2\,.\,3 \ldots\ldots n}$$

$$\therefore \Sigma\,u_{x+1} = \frac{x\,.\,(x+1)\,(x+2) \ldots\ldots (x+n)}{1\,.\,2\,.\,3 \ldots\ldots n+1}$$

$$\therefore S\,u_x = \frac{x\,(x+1)\,(x+2) \ldots\ldots (x+n)}{1\,.\,2\,.\,3 \ldots\ldots n+1}$$

which is a general formula for the figurates of any order.

The following theorem, established in the calculus of differences, is of considerable use in the summation of series.

Let the successive terms of the series be signified as before, and let x be the number of terms whose sum is required, so that

$$S\,u_x = u_1 + u_2 + u_3 \ldots\ldots + u_x$$

Let $D_1, D_2, D_3, \ldots\ldots$ be respectively the first terms of the *first, second, third*, &c. differences; then will the sum of x terms be expressed by

$$S\,u_x = x\,u_1 + \frac{x\,(x-1)}{1\,.\,2}\,D_1 + \frac{x\,(x-1)\,(x-2)}{1\,.\,2\,.\,3}\,D_2 + \frac{x\,(x-1)\,(x-2)\,(x-3)}{1\,.\,2\,.\,3\,.\,4}\,D_3 + \&c.$$

In all cases where we can arrive at a constant difference this series will be finite, and give the exact sum.

Ex. 1. Let the series be the squares of the successive integers.

$$S\,u_x = 1^2 + 2^2 + 3^2 \ldots\ldots x^2$$

$$\therefore u_1 = 1,\ D_1 = 3\ D_2 = 2\ D_3 = o$$

In this case D_2 is constant, and

$$S\,u_x = x + \frac{x\,(x-1)}{1\,.\,2}\,.\,3 + \frac{x\,(x-1)\,(x-2)}{1\,.\,2\,.\,3}\,.\,2.$$

Ex. 2. Let the series be the cubes of the successive integers.

$$S\,u_x = 1^3 + 2^3 + 3^3 + \ldots\ldots x^3$$

$$\therefore u_1 = 1,\ D_1 = 7\ D_2 = 12\ D_3 = 6\ D_4 = o$$

$$\therefore S\,u = x + \frac{x\,(x-1)}{1\,.\,2}\,.\,7 + \frac{x\,(x-1)\,(x-2)}{1\,.\,2\,.\,3}\,12 + \frac{x\,(x-1)\,(x-2)\,(x-3)}{1\,.\,2\,.\,3\,.\,4}\,.\,6$$

If we investigate this by the method of integration we shall obtain a remarkable result.

$$\Sigma\,(x+1)^3 = \frac{(x+1)^4}{4} - \frac{(x+1)^3}{3} + \frac{(x+1)^2}{4}$$

$$= \left(\frac{x\,(x+1)}{1\,.\,2}\right)^2$$

Hence we find

$$1^3 + 2^5 + 3^5 \ldots\ldots + x^3 = \left(\frac{x\,(x+1)}{1\,.\,2}\right)^2$$

But also

$$1 + 2 + 3 \ldots\ldots + x = \frac{x\,(x+1)}{1\,.\,2}$$

$$\therefore (1 + 2 + 3 \ldots\ldots + x)^2 = \left(\frac{x\,(x+1)}{1\,.\,2}\right)^2$$

$$\therefore 1^3 + 2^3 + 3^3 + \ldots\ldots + x^3 = (1 + 2 + 3 + \ldots\ldots + x)^2$$

(D. L.)

Serinagur, the name of a province in Nepaul, situated between East long. 77° and 80°, and North lat. 30° and 32°, and about 120 miles long, and 60 broad. The province consists generally of wooded hills and bare rocks, but the valleys, which are very confined, are highly fertile. The oak and most of the trees and fruits of Europe grow here, and wild elephants abound in the woods. The principal mineral productions are a good deal of copper and some gold.

The trade with the surrounding districts is carried on by means of sheep and goats, each of which carries about 12 lbs. of borax in a small sack. Flocks of 100 or 200 may be seen at a time, attended by shepherds and their dogs; and, conducted by a stout ram, having a large bell, they travel at the rate of 10 or 15 miles per day. Before the invasion of the state by the Nepaulese it was governed by a Hindoo prince, whose revenue was about L.65,000 per annum. In 1809, after a bloody battle fought at Guradwara, the Rajah of Nepaul made himself master of Serinagur, and held it in subjection by a military force. After the conquest of Nepaul by the British in 1816, the prince of Serinagur was re-established in his dominions, and the province may therefore be considered as under the British protection.

SERINAGUR is the capital of the above principality. The city stands in the centre of a valley 3 miles long, watered by the river Alcananda. It is about ¾ths of a mile long, and its streets are narrow and dirty. The houses, which are of rough stone and mud, are slated. With the exception of the palace of the Rajah, which is four stories, the houses are only two stories high. The river, which is crossed by a bridge of ropes, is only about 80 yards wide in the dry season. The celebrated temple of Ishwara stands on the opposite side of the river. With the exception of about 70 Mahomedan families, the inhabitants are chiefly Hindoos. During the rainy season foreigners quit the city on account of its insalubrity. East long. 79° 18′ North lat. 30° 11′.

SERINGAPATAM, or, Siri-runga-patan, a celebrated city of Hindoostan, and formerly capital of the province of Mysore. It is situated at the height of 2412 feet above the level of the sea, at the upper end of an island in the river Cavery, four miles long, and four and a half broad. The river is here five feet deep, and flows over a rocky bed. On the western side of this island stood the fortress, which occupied a space of 2000 yards, and contained magnificent palaces, lofty mosques, and regular outworks. Protected on its north and south sides by the river, a single rampart was found sufficient to defend this fort. But in 1792, the east and west faces, which were much weaker, were strengthened by double walls and ditches, by a circular work on the south east angle, by several formidable cavaliers, and by outworks before the gates. The rampart, which is very narrow, is from 20 to 35 feet high, and the whole of the revetement, with the exception of the north-west portico, consists of large oblong pieces of granite laid transversely in the walls with cement. A glacis of stone stretches along the northern face of the fortress, and the ditches are cut out of the solid rock. There are very few buildings of any importance within the fort, and those in the town are generally mean. The Sultan's palace is a magnificent building, in the Asiatic style of architecture; but it is deformed by a lofty wall, and the unfinished buildings which surround it. The great mosque, which is covered with the finest chunam, is adorned with lofty minarets. The ruins of the old Mysore palace have been converted into a military storehouse.

In the island is a celebrated temple dedicated to Vishnu, and in the beautiful garden called the Loll Bang, a handsome mausoleum, kept in repair by the Madras government, has been erected over the remains of Hyder Ally and his son Tippoo.

Before the siege of Seringapatam, (of which we have given some account in our article Mysore,) the population of the city and the island is said to have amounted to 150,000, including the garrison, but in the year following it was reduced to 32,000. Seringapatam now belongs to the British. It is the residence of a judge and collector, and is defended by a strong garrison. The mean annual temperature of this place is 77° 06. See *Edinburgh Journal of Science*, No. x. p. 249.

SERPENTINE. See Mineralogy Index, and also the *Edinburgh Transactions*, vol. x. part 1, and Dr. Brewster's *Journal of Science*, vol. i. p. 1, and vol. iii. p. 112, 126. The three interesting papers here referred to are by Mr. Haidinger, Mr. Lyell, and Mr. Herschel. See also Scotland.

SERTORIUS. See Roman Empire.

SERVETUS, Michael, a learned and unfortunate theologian, who has become celebrated principally from his having fallen a victim to the grossest religious intolerance. As we have given a full account of this transaction (which has been greatly misrepresented by the Anti-Calvinists) in our article Calvin, it is unnecessary to resume the subject at present.

Servetus was born at Villa Nueva in Arragon, in 1509, and he was burned at Geneva on the 27th October 1553.

He was not only an able man but a learned physician; and he is said to have made the nearest approach to the discovery of the circulation of the blood, having clearly mentioned the circulation of the blood through the lungs in his work *De Restitutione Christianismi*. A life of Servetus, in a series of letters to Dr. Morse from Dr. Vanderkemp will be found in the *Monthly Repository*, vol. v.

SERVIA, usually Mœsia Superior, is a province of Turkey in Europe. Belgrade, already described, is its capital. See Turkey.

SETTLE, a market town of England, in the west riding of Yorkshire, is situated on the eastern bank of the river Ribble, which is here crossed by a stone bridge. The principal street is built on the high road from Skipton to Kirby Lonsdale, and has several good stone houses. The smaller streets which branch from it to the north, are irregular and poorly built. The market place is spacious, and the church, which is a plain edifice, is at Giggleswick, on the other side of the river. The cotton mills here give employment to many of the inhabitants. The town stands very singularly at the bottom of an almost perpendicular limestone rock, the summit of which commands a fine prospect. Number of houses in the township in 1821 was 281. and the population 1508. See *The Beauties of England and Wales*, vol. vi.

SETUBAL or St. Ubes, anciently *Cedobriga*, a seaport town of Portugal in the province of Estramadura, situated in a bay of the Atlantic, at the mouth of the river Sandao. Having been destroyed in the earthquake of 1775, it was rebuilt in a better style, and contains several good streets with commodious houses. The whole of the town was fortified with a mound, a strong citadel called St. Philips with an excellent stream of water, besides the strong fort of Outao, and two small forts. There are in the town five churches, two hospitals, an arsenal, eleven monasteries, and an academy, founded by John V. It has a good harbour, capable of receiving any ships of burthen. It carries on a great export trade in lemons, olives, oil, Muscadel wine. but particularly bay salt, of which about 200,000 tons are annually made here, and sent to the north of Europe. In 1796, 551 vessels entered the harbour, and as many cleared out of it. Population 12,000. West Long. 8° 53′. North Lat. 38° 29′.

SEVASTAPOL, a seaport town of Russia in the Crimea, situated on a small bay of the Black Sea. After falling into the condition of a Tartar village, from being one of the principal towns of ancient Colchis, it has again risen into importance as a station of the Russian fleet. Its harbour is ranked with those of Malta and Port Mahon, and it is furnished with docks, dock yards, an arsenal. barracks, and a lazaretto. The chief bay runs about 700 fathoms into the land, and has a depth of about 10½ fathoms. It is wholly free of shoals, and is completely sheltered. This place has increased very rapidly. Population about 9000. East Long. 34° 11′. North Lat. 43° 41′ 30″.

SEVEN Oaks, a market town of England, in Kent, is situated on a gentle eminence, near the river Derwent. The town consists chiefly of two spacious streets in the form of the letter Y. Many of the houses are large and respectable looking buildings, inhabited by families in independent circumstances. The ancient market house stands near the middle of the High Street. The church, which has an elevated situation at the south end of the town, is a large and handsome edifice, and forms a conspicuous object for many miles around. The charitable establishments are an hospital and free grammar school, founded by William de Sevenoke, Lord Mayor of London in 1441. He is said to have been found on the streets, and educated by a person of this town. It was subsequently farther endowed by Queen Elizabeth, and is said to have a revenue of £800 a year. It possesses six exhibitions to either of the Universities. About thirty-two elderly trades people find an asylum in the hospital, which has also sixteen out-pensioners. Mills have lately been established here for weaving silk, which give employment to many of the inhabitants. The town house derives its chief support from the constant influx of company on their way to Tunbridge. Population of the town about 1600. See Hasted's *History of Kent*, and the *Beauties of England and Wales*, vol. viii.

SEVERN, Vale of the. See England.

SEVERUS. See Roman Empire.

SEVIER, county of the United States in Tennessee, traversed by French Broad, and drained in part by Pigeon river; bounded SE. by Smoky mountain or North Carolina; SW. by Blount county of Tennessee, NW. by Knox, NE. by Jefferson, and E. by Cocke counties. Length 33, mean breadth 20, area 660 square miles. Surface hilly and might be designated mountainous. Chief town Sevierville. Central lat. 35° 50′ N.; long. W. from Washington City 6° 34′. Sevierville stands on Pigeon river twenty-five miles NE. by E. from Knoxville, N. lat. 31° 52′.

Darby.

SEVILLE, anciently Hispalis, a large city of Spain, in Andalusia. It is situated on a beautiful and extensive plain on the banks of the Gaudalquivir. The city is of a circular form, and is surrounded by an old and high wall, consisting of indurated cement, about five or six feet in circumference, flanked with 176 turrets, and entered by 12 gates. The interior of the city is chiefly built in the Moorish style, the streets being so narrow that a person extending his arms can touch the houses on either side. The streets are crooked and ill paved, though the houses are tolerably well built. Many of the houses have large courts with a fountain in the centre, and are surrounded with galleries, in which the families live in summer when they do not spread tents in the courts. The houses, though highly embellished in the interior, have a very mean aspect when seen from the streets.

Seville contains many fine public buildings, 30 churches, 84 convents, and 24 hospitals, besides the edifices for civil and commercial purposes. The cathedral is a magnificent pile of Gothic building, erected in 1401. Its tower, 250 feet high, is deemed the finest in Spain. It was built in 1568, and is of such easy ascent, and so wide, that two horsemen may ride up abreast. On the top of it is the Giralda, a brazen image, which, with its palm branch, weighs about 1½ tons, yet moves with the slightest change of wind. The cathedral is 420 feet long by 263 wide, and its height is 126 feet. It is lighted by 80 windows with painted glass, executed by Arnao of Flanders. It contained 82 altars. The treasures of this church were, before the revolution, of considerable value; but we fear that its fine pictures, its extensive library, and its decorations of gold, silver, and precious stones, have been plundered by its merciless invaders. The organ has 50 pipes more than the famous one at Haerlem, and it is filled with air by a man walking backwards and forwards on an inclined plane. When the different pair of bellows are thus filled they supply the full organ 15 minutes.

Many of the monasteries in Seville are distinguished for their architectural beauty: that which belongs to the Franciscans is on the most extensive scale; of its 15 cloisters many are spacious and elegant, with apartments for 200 monks. The convent of Buenavista, on the opposite side of the Guadalquivir, commands a view of the mountains of Benda 70 miles distant, and of the Sierra Morena equally remote. The hospital of La Sangre, intended for female patients, is much admired for its front, which has sculptured upon it three fine figures of Faith, Hope, and Charity. The wards are spacious, and the whole establishment is remarkable for its neatness.

The principal secular buildings are the Alcazar or royal palace, built by the Moors, the Lonja or Exchange, the Roman aqueduct, the Torre del Ore, and the Plaza de Toros. The Alcazar, erected by the Moors, and extended by several Christian princes, is a spacious building, having a mean external appearance. Its interior contains various courts, with galleries, fountains, and baths. The garden, decorated with fountains and evergreens, has its walks paved with marble, and is said to have undergone no change since the time of the Moors. A collection of Roman antiquities brought from the ancient town of Italica in the neighbourhood, occupies one of the saloons. The Lonja or Exchange, designated by Herera in 1568, is an edifice of the Tuscan order, finely situated in the centre of a square. It is a quadrangle of 200 feet, having round it a corridor or spacious gallery, decorated with Ionic, and supported with the same number of Doric columns. Though built for an exchange, it has been used as a repository of the old official correspondence with America, which contains collections of letters from Cortez, Pizarro, and other Spanish generals. The aqueduct, or Canos de Carmone, built in the time of the Romans, brings water to the city from a distance of *eight* miles, and has 410 arches. According to Mr. Swinburne, it is ugly and crooked, the arches are unequal, and the architecture neglected. The conduit is so leaky that a rivulet is formed by the waste water, and yet the supply is so copious as to afford water to several mills, and give almost every house in town the benefit of it. There is still preserved here a large house, the residence of a Moorish chief, in perfect preservation. The walls are adorned with a sort of network, and the workmanship on plaster is without a flaw, though above *five* centuries old.

The university of Seville was founded in 1502, and counted among its members the celebrated Arius Montanus. The discoveries and improvements of modern science have not yet enlightened this seat of learning. The number of under graduates is extended to about 200. There is an institution here called St. Elmo, founded by the son of Christopher Columbus, and appropriated to the education of young men for the sea. There is also here an academy for the arts of painting, sculpture, and architecture, and an œconomical society, both of which were founded by Count Campomanes. About 200 pupils attend the first of these institutions.

Seville was long celebrated for its silk manufactures, but they declined in the middle and end of the 17th century. The number of looms lately at work is about 2500, the silk being brought from Granada and Valencia. The other articles of manufacture are coarse woollen cloths, leather, tobacco and snuff. The snuff manufactory belongs to government, and occupies a large building 200 yards long by 185 broad. The interior consists of 28 courts, round which are disposed the various apartments. Horses and mules are employed to drive the mills, which amount to 100. There is also a cannon foundry here belonging to government.

After the discovery of America, the monopoly of its trade was conferred on Seville, but owing to the obstruction which vessels of burden experienced in the navigation of the Guadalquivir, this monopoly was transferred to Cadiz. Large vessels are stopped at Lucar, the very mouth of the river, and those drawing more than ten feet of water are obliged to load and unload eight miles below Seville. The principal exports are wool, goat and kid skins, oranges, liquorice, oil and silk. The liquorice exported is nearly 200 tons, and a considerable part of it is said to be purchased by the London porter brewers. The articles imported are English manufactures, Nuremberg wares, Bilboa iron, and articles of colonial produce from South America. The country round Seville is very fertile, but the climate is insalubrious, generating agues and malignant fevers. The scorching solano from the African deserts is beyond measure oppressive in summer.

Seville has well built suburbs, one of which called Triana, on the west side of the river, has a communication with the city by a bridge of boats. The handsome promenade called Alameda, has three walks planted with trees, and is ornamented with seats and fountains.

The population of the city is stated by Townsend at 80,268, by Laborde at 96,000, and by others at 100,000. West long. 5° 38′ 37″. North lat. 37° 24′ 26″. See Townsend's *Travels in Spain*, Laborde's *View of Spain*, Burgoanne's *Travels*, and Swinburne's *Travels*.

SEVRES, Department of the Two, a department in the north-west of France, embracing about a third of the old province of Poitou. It is bounded by the departments of the Meuse and Loire, on the north; by that of Charente and Lower Charente, on the south; by that of Vendèe, on the east; and by Vienne, on the west. Its superficial extent is 585,273 hectares, or about 2500 square miles. It is traversed from N. E. to S. W. by a chain of lofty wooded mountains. The south-west part of it is marshy; but the rest of the department has a very fertile soil, which produces wheat, barley, rye, oats, buck wheat, and maize. Tobacco is partially cultivated. Chesnuts abound in different places; almonds occur in warm aspects, and hops grow wild in the neighbourhood of Niort. The pasturage is good, and horses, cattle, and sheep are reared in considerable numbers. The department is watered by the two Sevres, the Dive, the Loire, the Thoue, and other smaller streams. Among the valuable minerals are iron, antimony, saltpetre, marble, &c. The manufactures consist of pottery, woollen, and cotton goods, leather, saltpetre, and paper. The principal towns are Niort the capital, with 16,000 inhabitants, Parthenay, with 3213, Thouars, with 2035, and Melle, with 1800.

Population in 1822	.	.	279,845
Ditto in 1827	.	.	288,240
Increase in five years	-	-	8,395

There are 490 inhabitants for every 100 hectares.

SEXTANT.

Sextant is the name given to a graduated instrument, the divided arch of which is, in place of being a whole arch, or a Quadrant, only a *sextans*, or sixth part of a circle.

Instruments, whose divided limb is a whole circle, have been already fully described in our article Circle; and those which are only the quarter of a circle, have been described under the article Quadrant. We shall therefore limit ourselves at present to an account of Hadley's sextant, and other analogous instruments which have been invented since the preceding articles have been published, together with a description of the various artificial horizons.

CHAP. I.

DESCRIPTION OF SEXTANTS.

The history of the sextant having been already detailed in our article on Navigation, we shall add nothing farther on this subject, but proceed to the description of Hadley's instrument.

Section I.—*Description and use of Hadley's Sextant.*

This valuable instrument is shown in Fig. 5 of Plate CCCCLXXXVII. The contrivance of it is founded on this obvious principle in Catoptrics: that if the rays of light diverging from, or converging to, any point, be reflected by a plane polished surface, they will, after the reflection, diverge from or converge to another point on the opposite side of that surface, at the same distance from it as the first; and that a line perpendicular to the surface passing through one of these points, will pass through both. Hence it follows, that if the rays of light emitted from any point of an object be successively reflected from two such polished surfaces, then a third plane, perpendicular to them both, passing through the emitting point, will also pass through each of its two successive images made by the reflections; and that these three points will be at equal distances from the common intersection of the three planes: and if two lines be drawn through that common intersection, one from the original point in the object, the other from that image of it which is made by the second reflection, they will comprehend an angle double that of the inclination of the two polished surfaces.

Let RFH and RGI, Plate CCCCLXXXVII. Fig. 3. represent the sections of the plane of the figure by the polished surfaces of the two specula BC and DE, erected perpendicularly thereon, meeting at R: which will be the point where their common sections, perpendicular likewise to the same plane, passes it; and HRI is the angle of their inclination. Let AF be a ray of light from any point of an object A falling on the point F of the first speculum BC, and thence reflected into the line FG, and at the point G of the second speculum DE, reflected again into the line GK, produce GF and KG backwards to M and N, the two successive representations of the point A; and draw RA, RM, and RN.

Since the point A is in the plane of the figure, the point M will be so also, by the known laws of Catoptrics. The line FM is equal to FA, and the angle MFA double the angle HFA, or MFH; consequently RM is equal to RA, and the angle MRA double the angle HRA, or MRH. In the same manner the point N is also in the plane of the figure, the line RN equal to RM, and the angle MRN double the angle MRI, or IRN; subtract the angle MRA from the angle MRN, and the angle ARN remains equal to double the difference of the angles MRI and MRH, or double the angle HRI, by which the surface of the speculum DE is reclined from that of BC; and the lines RA, RM, and RN are equal.

Corol. 1. The image N will continue in the same point, although the two specula be turned together circularly on the axis R, so long as the point A remains elevated on the surface of BC: provided they retain the same inclination.

Corol. 2. If the eye be placed at L, (the point where the line AF continued cuts the line GK;) the points A and N will appear to it at the angular distance ALN, which will be equal to ARN. For the angle ALN is the difference of the angles FGN and GFL; and FGN is double FGI, and GFL double GFR, and consequently their difference double FRG or HRI, therefore L is in the circumference of a circle passing through A, N, and R.

Corol. 3. If the distance AR be infinite, those points A and N will appear at the same angular distance, in whatever points of the figure the eye and specula are placed, provided the inclination of their surfaces remains unaltered, and their common section parallel to itself.

Corol. 4. All the parts of any object will appear to an eye viewing them by the two successive reflexions as before described, in the same situation as if they had been turned together circularly round the axis at R, (keeping their respective distances from one another, and from the axis,) with the direction HI, *i. e.* the same way the second speculum DE reclines from the first BC.

Corol. 5. If the specula be supposed to be at the centre of an infinite sphere, objects in the circumference of a great circle, to which their common section is perpendicular, will appear removed by the two reflexions, through an arch of that circle, equal to twice the inclination of the specula, as before said. But objects at a distance from that circle will appear removed through the similar arch of a parallel; therefore the change of their apparent place will be measured by an arch of a great circle, whose chord is to the chord of the arch equal to double the inclination of the specula, as the cosines of their respective distances from that circle are to the radius; and if these distances are very small, the difference between the apparent translation of any one of these objects, and the translation of those which are in the circumference of the great circle aforesaid, will be to an arch equal to the versed sine of the distance of this object from that circle, nearly as double the sine of the angle of inclination of the specula, is to the cosine of the same.

For let OBC, Fig. 4. in the annexed figure, represent an infinite sphere, at whose centre R are placed the two specula inclined to one another in any given angle, and let their common section coincide with the diameter ORC. Let BAN be the circumference of a great circle, to the plane of which the common section of the specula ORC is perpendicular, and BR its radius; let *b a n* be the circumference of a circle parallel to BAN, and at the distance from it B *b*; draw *b* D the sine, and *b r* the cosine of the arch B *b*; BD is the versed sine of the same.

Let A be a point of an object placed in the circumference of the great circle BAN, and N the point in which its image is formed by the two successive reflexions as before described; and let *a* be a point of another object placed any where in the circumference of the parallel *b a n*, and *n* its image; and let *a b n* be an arch of a great circle passing through the points *a* and *n*. The point *a* is at the same distance from the great circle BAN, as the point *b*, *i. e.* at the distance B *b*. Draw AR, AN, RN, *a r*, *a n*, *r n*, *a* R, and *n* R.

By the fourth corollary the figures ARN and *a r n* are similar, and consequently the line AN is to the line *a n* as AR or BR is to *a r* or *b r*, *i. e.* as the radius is to the cosine of the distance B *b*. But AN is the chord of the arch AHN of the great circle BAN, equal to the translation of the point A, or double the inclination of the specula, and *a n* is the chord of the arch *a h n* of a great circle measuring the angle *a* R *n*, by which the point *a* appears removed by the two reflexions, to an eye placed in the centre R. Therefore the translation, or apparent change of place, of the point *a* is measured by an arch of a great circle, whose chord is to the chord of the arch AHN, (equal to double the inclination of the specula,) as the cosine of its distance from the great circle BAN is to the radius.

From any point C of the circumference OBC draw the chords CN and C *m*, to the same side of the point C, and equal to the chords AN and *a n* respectively, draw the radius RM, and from R and *m* draw RQ and *m* P, both perpendicular to CM, and cutting it in Q and P. RQ is the cosine, and CM double the sine of half the angle MRG, or ARN, or of the angle of inclination of the specula. The little arch M *m* will represent the difference of the apparent translations of the objects in A and *a*; and if it be very small, may be looked on as a straight line, and the little mixed triangle M *m* P as a rectilinear one, which will be similar to RMQ, because RM is perpendicular to M *m* and RQ to CM, and the angles at Q and P right angles.

The line CP may be taken as equal to C *m* and MP as the difference of the lines CM and C *m*. Therefore the little arch M *m* is to the line MP nearly as RM to RQ; but CM (*i. e.* AN) was to C *m* (*i. e.* *a n*) as BR to *b r*, and the difference MP, of CM and C *m*, to the difference BD of BR and *b r*, as CM to BR. Therefore M *m*, the difference of the apparent translations, is to BD, the versed sine of the distance B *b*, or to an arch equal to it, in the compound ratio of RM the radius to RQ, the cosine of the angle of inclination of the specula, and CM double the sine of the same to BR the radius, *i. e.* as CM to RQ.

The observation may be corrected by one easy operation in trigonometry, as will appear from the first part of this corollary, viz. by taking the half of the angle observed and then finding another angle whose sine is to the sine of that half, as the cosine of the distance B *b* is to the radius: this angle doubled, will be the true distance of the object. But as this operation, though easy, will require the use of figures, the method of approximation is better, because by that, the observer retaining in his memory the proportion of the sines of a few particular arches to the radius, may easily estimate the correction without figures, when the angle is not great, and by a line of artificial numbers and sines, may always determine it with greater exactness than will ever be necessary.

When the angle observed is very near 180 degrees, the correction may be omitted; for then it will be easy to keep the plane of the instrument so near that of the before mentioned great circle, as not to want any, if the situation of that circle be known; if it be not, the observer, when he sees the two objects together, may turn the instrument on the axis of the telescope till he finds that position of it by which he obtains the least angle; and this (if the specula are set truly perpendicular to the plane of the instrument) will always happen when the objects appear to coincide in the line *g h*, as expressed in the figure.

The instrument consists of an octant ABC, Figure 5, having on its limb BC, an arch of 45 degrees, divided into 90 parts or half degrees, each of which answers to a whole degree in the observation. It has an index ML moveable round the centre to mark the divisions; and upon this, near the centre, is fixed a plane speculum EF perpendicular to the plane of the instrument, and making such an angle with a line drawn along the middle of the index, as will be most convenient for the particular uses the instrument is designed for; (for an instrument made according to Figure 5, the angle LFM may be of about 65 degrees.) IKGH is another smaller plane speculum, fixed on such part of the octant as will likewise be determined by its particular use, and having its surface in such direction, that when the index is brought to mark the beginning of the divisions (*i. e.* 0°) may be exactly parallel to that of the other; this speculum being turned towards the observer and the other from him. PR is a telescope, fixed on one side of the octant, having its axis parallel to that side, and passing near the middle of one of the edges IK or IH of the speculum IKGH; so that half its object glass may receive the rays reflected from that speculum, and the other half remain clear to receive them from a distant object. The two specula must also be disposed in such a manner that a ray of light coming from a point near the middle of the first speculum may fall on the middle of the second in an angle of 70 degrees or thereabouts, and be thence reflected into a line parallel to the axis of the telescope, and that a clear passage be left for the rays coming from the object to the speculum EF by the side HG. ST is a dark glass fixed in a frame, which turns on the pin V; by which means it may be placed before the speculum EF, when the light of one of the objects is too strong: of these there may be several. In the distinct base of the telescope represented by the circle *a b c d e f*, are placed three hairs, two of which, *a c* and *b d*, are at equal distances from and parallel to the line *g h*, which passes through the axis, and is parallel to the plane of the octant: the third *f c* is perpendicular to *g h* through the axis.

The instrument, as thus described, will serve to take any angle not greater than 90 degrees: but if it be designed for angles from 90 to 180 degrees, the polished surface of the speculum EF, Figure 5, must be turned towards the observer; the second IKGH must be brought forward to the position NO so as to receive on its middle the rays of light from the middle of the first, in an angle about 25 degrees, their surfaces being perpendicular to one another when the index is brought to the end of the divided arch next C; and this second must stand five or six inches wide of the first, that the head of the observer may not intercept the rays in their passage towards it, when the angle to be observed is near 180°. The smaller speculum is fixed perpendicularly on a round brass plate, toothed on the edge, and may be adjusted by an endless screw.

In order to make an observation, the axis of the telescope is to be directed towards one of the objects, the plane of the instrument passing as near as may be through the other, which must lie to that hand of the observer as the particular form of the instrument may require; viz. the same way that the speculum FF does from IKGH, if it be composed according to this figure and description. The general rule is, that when the index is brought to the beginning of the scale, (*i. e.* to 0° when the instrument is designed for angles under 90°, or to 90° when it is designed for angles from 90° to 180°); if then a line be imagined to be drawn on it, parallel to the axis of the telescope, or line of direction of the sight, so as to point towards the object seen directly; whichever way this line is carried by the motion of the index along the arch from 0° toward 90° in the first case, or from 90° towards 180° in the second, the same way the object seen by reflexion ought to lie from that which is seen directly. The observer's eye being applied to the telescope, so as to keep sight of the first object; the index must be moved backward and forward till the second object is likewise brought to appear through the telescope, about the same distance from the hair *c f* (Figure 6) as the first: if then the objects appear wide of one another, as at *i* and *k*, the instrument must be turned a little on the axis of the telescope, till they come even or very nearly so, and the index must be removed till they unite in one, or appear close to one another in a line parallel to *c f*, both of them being kept as near the line *g h* as they can. If the instrument be then turned a little on any axis perpendicular to its plane, the two images will move along a line parallel to *g h*, but keep the same position in respect of one another; so that in whatever part of that line they may be observed, the accuracy of the observation will be no otherwise affected than by the indistinctness of the objects. If the two objects be not in the plane of the instrument, but equally elevated on, or depressed below it, they will appear together at a distance from the line *g h*, when the index makes an angle something greater than their nearest distance in a great circle; and the error of the observation will increase nearly in proportion to the square of their distance from that line, but may be corrected by help of the fifth corollary. Suppose the hairs *a e* and *b d*, each at a distance from the line *g h*, equal to $\frac{100}{1146}$ of the focal length of the object-glass, so as to comprehend between them the image of an object whose breadth to the naked eye is a little more than 2°¼; and let the images of the objects appear united at either of those hairs; then as the cosine of half the degrees and minutes marked by the index is to the doubled sine of the same, so is one minute to the error which is always to be subtracted from the observation. Other hairs may also be placed in the area *a b c d e f*, parallel to *g h*, and at distances from it proportional to the square roots of the numbers 1, 2, 3, 4. &c. and then the errors to be subtracted from the same observation made at each of those hairs respectively will be in proportion to the numbers 1, 2, 3, 4, &c. This correction will always be exact enough if the observer takes care (especially when the angle comes near 180°) to keep the plane of the instrument from varying too much from the great circle passing through the objects. When the angle is very near 180° the correction may be omitted, for then it will be easy to keep the plane of the instrument so near that of the before mentioned great circle, as not to want any, if the situation of that circle be known; if it be not, the observer, when he sees the two objects together, may turn the instrument on the axis of the telescope till he finds that position of it by which he obtains the least angle; which (if the specula are set truly perpendicular to the plane of the instrument) will always happen where the objects appear to coincide in the line *g h*, as shown in Fig. 6.

Such is Mr. Hadley's own description of the original sea octant, as it was called, for measuring the distances of the sun and moon from any of the fixed stars, for which purpose he proposed that it should be placed upon a stand. He has described, however, a modification of it, by which it may be held in the hand without any other support, and in which the telescope is to magnify four or five times. The object of this was to measure the altitude of the sun, moon, and stars, from the visible horizon at sea. It differed from the foregoing instrument, chiefly in placing the specula and telescope with regard to the sector and tubes. In the new form the line drawn along the middle of the index falls on the anterior surface of the larger speculum at an angle of about 4 or 5 degrees. The axis of the telescope or the line of sight falls on the surface of the second speculum at an angle of about 70 or 71 degrees. It has also a third speculum, to be used when the angle is greater than 90 degrees, for observing the sun's altitude, by means of the opposite part of the horizon. On this the line of direction of the sight falls at an angle of about 32 or 33 degrees.

Various improvements on this admirable instrument have been made since the time of its invention. Grant, Ewing, Dollond, Magellan, Ramsden, Mayer, Borda, and some of our living artists, have also improved it. It has been modified in various ways; but whether it is in the form of a quadrant, a sextant, or a circle, the principle is always the same, viz. the reflexion of mirrors placed at different distances on the plane of the instrument. In our article CIRCLE, the reader will find the fullest details of all the most important improvements which the reflecting circle has undergone. Hadley's quadrant, as now fitted up, and the method of using it, is shown in Fig. 7, where FG is the divided limb, EH the moveable index, E the index-glass or mirror, D the horizon-glass, and *b* the sight or eye-hole, where the eye of the observer is applied. When a telescope is used, it is placed in the position *b*B. The horizon-glass consists of a transparent half, and a reflecting half, as described by Hadley. In taking the altitude of the sun, let BA be the visible horizon, and S the sun. The sun's rays SCE fall on the mirror at E, which is turned round, by moving the index EH till the ray ED, which it reflects, reaches the eye at B, after a second reflexion from the reflecting half of the horizon-glass D. The observer then keeps moving the index, till the lower or upper limb of the sun thus seen by reflexion is coincident with or touches the visible horizon. The vernier H on the index will thus point out the altitude of the limb of the sun observed.* If S is the moon, and A a fixed star, the limb of the moon is brought to touch the star in the same manner, and their distance is thus obtained. When it is required to measure an angle between 90 and 180 degrees, a second fixed speculum is placed at K, so as to be at right angles to the moveable one E in its remotest situation. It will then produce a deviation of two right angles in one of the objects. Thus if *s* is a star, and *a* another star nearly opposite to it, the ray *s* E will be reflected in the direction EK, and again in the direction K *e* to the eye at *e*, which carries it in the direction *e a*. This is called the back observation, which is of great use when coasting along shores which intercept the horizon of the sea, on the side in which the sun is; but the difficulties attending the rectification of the mirrors is so great that they are rarely used, and are even suppressed upon most sextants.†

When the sun is obscured, or when the light of one of the objects is stronger than that of the other, the light is reduced by coloured glasses placed between E and D, as shown at C in Fig. 14, or between E and K.

II. *Description of Professor Amici's Prismatic Sextant.*

This very ingenious instrument is represented in Plate CCCCLXXXVII, Figs. 8, 9, 10. In Fig. 8. ABC is a prism placed before the object glass E, so that its base AB is in a line with the axis of the telescope directed to the distant object Q. The parallel rays from the object falling upon the face BC, will be refracted towards the base BA, where they will be totally reflected, and will emerge from the face AC in lines parallel to their first direction. These rays falling upon the object glass E of a telescope, will form an image of the object Q, which will coincide with the direct image of the same object formed by the rays which pass below the prism. This coincidence will give the zero of the scale which measures the angular separation of these two images. If the prism is now turned round its edge A in the direction BCA, it will show new objects in succession coincident with the object Q, until the side AC shall be parallel to the object glass E. We shall now have the super-position of all those points that are 90° distant from the point Q, and therefore it is evident that we can thus measure all angular distances as far as 90° and a little more, as far indeed as 102° with common glass.

If we now place before the other half of the object glass a second prism equal to the first, but moveable in a contrary direction, the two images of Q will be both seen by reflexion; and by the continued movements of the two prisms we can carry the measure of an angle to the double of the greatest angle measured by one prism alone, that is to 204°, if the prism is of common glass.

From this theory of the new sextant, its construction and use will be readily understood. In the perspective drawing of it in Fig. 9, ABD is a sector, greater than a quadrant, of four inches radius. It is divided into 10', which by a vernier is subdivided into 10″. Round the centre C revolves the index CE, which carries the vernier at one end, and the isosceles rectangular prism F at the other, with its edge SC directed to the centre, and perpendicular to the plane of the limb. The other prism H, similar to the first, is fixed on the instrument, so that when the index marks *zero*, the larger faces of the two prisms are perfectly parallel, and nearly in contact. A telescope N on the arm IL is moved about the centre C, and on the plane of the sector. The divisions are read off by a microscope M. By this double motion of the telescope parallel to the limb, the object glass can receive a greater quantity of rays from one prism than from the other, so that we may by this means render the images of two objects equally luminous when they happen to be of different brightnesses. This effect is similar to what is obtained in Hadley's sextant by the elevation or depression of the telescope on the limb. If an equality of light is not thus obtained, we must apply to the object glass of the telescope the cover A', half of the aperture of which remains uncovered, while the other half is filled with a plain coloured glass. This glass being turned towards the prism which reflects the most luminous object, will enable us to obtain the necessary equalization of the light.

The error of collimation may be detected in this instrument in three different ways.

1. By the coincidence of the two images of the same object, the one direct and the other reflected. The sun's disk is the best object, but any terrestrial object will answer if more than 100 yards distant, for at this distance the parallax becomes visible.

2. By the coincidence of two images of the same object externally reflected from two small faces of the prism, for when the two isosceles and rectangular prisms having their greater sides parallel at zero, have their smaller sides parallel so as to give coincident images, we have an angle of 90°.

3. By measuring two angular distances of two objects diametrically opposite to each other. The excess or defect of the sum of these two angles upon 180°, will give half the angle to be added to or subtracted from the zero point given by the vernier, in order to have the true zero or the error of collimation.

If we compare this last verification with the first, and find a difference, it must arise from an error in the division of the limb.

If the telescope is inclined to the common section of the reflecting planes of the prisms, the fourth part of the trangle will have for its sine, the sine of the fourth part of the angle given by the instrument multiplied by the cosine of the inclination of the axis.

* See OPTICS.

† See an account of the Rev. Mr. Ward's Method for the Back Observation in the *Gentleman's Magazine*, vol. lxxiv. or in the *Naval Chronicle*, 1805, vol. xiv. p. 21.

Let SR, ST be the two reflecting planes, whose common section is SQ; let SV bisect the angle of the two planes, let AB be perpendicular SQ and AD = AB = 1. From D let fall DH perpendicular to BA, and from D and B the perpendiculars DE and BC upon SB, and draw EA, CA, and HF parallel CB. Now if BA is the axis of the telescope, the angle formed by two coincident objects by reflexion, is quadruple the angle CAB, or twice the motion of the index. But if the angle has the obliquity DA, the true angle is the quadruple of the angle DAF, although the index gives the same angle as it had marked before. To find the error then, it is sufficient to determine the value of the angle DAE by means of the known angles CAB and BAD. By this construction we have AH : HE = AB : BC, or since HF = DE cos DAH : sin. DAE = 1 : sin. CAB, we have sin. DAE = sin. CAB cos. DAH. From this formula it appears that the greatest error must take place when CAB is 45°. In this case, if the axis of the telescope is inclined 1°, the angle observed will be 179°, 57′, 56″, instead of 180°; but this error, produced by a defective position of the telescope, is reduced to nothing, if we make the observation in that part of the field of the telescope where the slightest contact of the objects takes place.

The advantages of this instrument may be thus enumerated.

1. While the greater number of the sextants now made measure only to 124°. Amici's sextant can measure 180°. The former will not take double meridian altitudes of the sun at Genoa from the 7th May till the 8th August, and under the equator they can never be used for this purpose, but the latter will take their altitudes under the tropics and even at the zenith.

2. The points *zero* and 90 degrees can be verified in Amici's sextant.

3. When an artificial horizon is used, the telescope always rests in a horizontal position, so that the observer may sit at his ease before it, whatever be the altitude of the star he is observing.

4. At sea we may take all the altitudes of two opposite horizons, both the anterior and the posterior, the mean of which will correct the inequalities of refraction.

5. In Hadley's mirrors fully one half of the light is lost by reflexion, whereas in the prisms very little light is lost.

6. The mirrors are subject to flaws and cracks, and sometimes to the loss of the quicksilver, whereas nothing can injure the prisms unless a force which breaks them to pieces.

7. Amici's sextant has no parallax for objects near the observer, owing to the great proximity of the prisms.

8. The greatest of all advantages is, that we can make the *back observation* with Amici's instrument without adding a third prism. See Baron Zach's *Correspondence Astronomique*, vol. vi. p. 554.

Chap. II.—on artificial horizons.

In observing the altitudes of celestial bodies, it is necessary to see the apparent horizon, but as this is always obscured in foggy weather, and sometimes even in clear weather cannot be seen from the interposition of the coast, or an island, it became of great consequence to be possessed of what is called an artificial horizon. These have been constructed of a great variety of forms, such as vessels filled with mercury, oil, or tar, pendulums, plumb lines, and levels; some of the most useful of these we shall proceed to describe.

Sect. I.—*On the Common Fluid Artificial Horizon.*

The common artificial horizon consists of a shallow vessel nearly filled with mercury, or with any viscid fluid, such as treacle, tar, oil, &c. Instead of using a fluid, Troughton makes them of black glass, as in Fig. 11. and levels them by means of the screws SSS, with a bubble laid upon the surface. Dollond constructs them as in Fig. 12. with a plate *m n* of clear glass, concave beneath, and filled with spirits *p* 9. so as to serve as a level. These two forms of the horizon are preferable in cases where the tremor disturbs the mercury or treacle. The method of using the artificial horizon is shown in Fig. 13. where KL is the horizon and *e f g* the sextant. The image of the sun reflected at *b* from the mercury or tar passes through the horizon glass *d* to the eye at M, and is made to coincide with the image of the sun reflected from the index glass *e*, and seen by the eye at M. The angle thus measured is RM *b*, which will be twice the angle S *b* K or RSL. In Fig. 7. with the real horizon the angle observed is 35°, but in Fig. 13, with the artificial horizon, the angle is 70°. The artificial horizon will answer only for objects at a very great distance, as there will be a parallax corresponding to its distance MO from the eye.

In windy weather it is necessary to protect the surface of the mercury or tar from being ruffled by means of a cover or roof, MNO, Fig. 14, consisting of two plates, MN, MO, of parallel glass inclined nearly at right angles. After one observation the roof should be reversed, and another observation made in order to correct any error arising from want of parallelism in the surface of the plates of glass.

Sect. II.—*Description of Serson's Nautical Top.*

Mr. Serson who was lost on board his majesty's ship Victory about the middle of the last century, observed that when a top was spun, its upper surface directed itself in the course of two minutes after it was set up in a true horizontal plane: that this plane was not at all disturbed by any inclination or motion of the box on which it was placed, and therefore that it might be of great advantage as an artificial horizon.* When it was spun in the open air it continued 35 minutes in motion, but when it revolved in vacuo its motion lasted *two hours and sixteen minutes*, preserving itself perfectly horizontal for three quarters of an hour.

Serson's top, which is represented in Fig. 15. consists of three parts, the top itself, CD revolving on the pivot *p* at the end of the vertical axis P *p*; the agate cup MN in which it revolves, and the apparatus AB by which it is put in motion. The top CD is a hollow cylinder about 2¼ inches in diameter, and 2 inches high, the upper surface is a speculum, and

* *Philosophical. Transactions*, 1750. Vol. xlvii. p. 352.

the lower edge has a small rim inside to make it heavier. The axis P p is square at top, and the pivot p a cone of about 60°, and made of very hard steel. The cup of agate is about an inch in radius. When it is in use the whole is placed in a mahogany box, and a cover of glass is put on to keep off the wind.

In order to put it in motion, the brass frame AB rests with steady pins upon the edge of the mahogany box, so that the spindle S s is immediately above P, the lower end s of the spindle is a hollow square, which receives the square end P of the axis. The spindle S s has always a tendency to rise up by the action of the spring L through which it passes, the four prongs of the spring resting on the top of the frame. A lever E is brought over the knob S, at the top of the spindle, and keeps the spindle down so as to bring its lower end upon P. A ribband HG passes through a hole in the lever G, shown separately; and the end G of the ribband being put into the hole K in the spindle S s, the ribband is coiled round the spindle. It is then pulled by the end H, so as to put the spindle and the top in rapid motion, and when G quits K it pulls back the lever GF, and consequently draws the lever E from the top S of the spindle, so as to permit the spindle to rise by the action of the spring L, and quit the axis P of the top, which it leaves in rapid rotation.

This top, as made by more than one of the best artists, was tried at sea above 60 years ago by some of the first naval officers, but the hopes of success which were entertained were disappointed.

Mr. Weir, many years afterwards, revived this subject, and his instrument, made by the order, and at the expense of the board of Longitude, was tried in a king's ship by himself and an astronomer appointed by the admiralty. It was found that when the ship had any motion, the top could not be depended on, to the amount of several degrees, although it performed on shore to a smaller number of minutes. Mr. Weir's machine required a man to keep it in motion while observations were made with it. The reflecting surface was fully 12 inches in diameter. The glass rested its weight on a blunt point supported from a chest below. The train of wheels that gave motion to the glass were connected to the latter by means of leather thongs; and the motion of the ship stretching one of the thongs, and relaxing the opposite one, drew the glass from its due position through the angle above mentioned.

About the beginning of 1818, Mr. Troughton began his experiments on the nautical top. His first efforts were very flattering; for by means of an easy adjustment, he brought the planes of reflexion and rotation parallel to each other, which it requires good workmanship to effect. The form which Mr. Troughton gave to the top was that of a hollow cylinder of brass, open at the bottom, and terminated above by a circle of dark glass. The inner diameter of the cylinder was $4\frac{1}{2}$ inches, the outer diameter $4\frac{6}{10}$ inches, its height $1\frac{1}{2}$ inch, and the diameter of the reflecting glass $4\frac{1}{2}$ inches. Mr. Troughton afterwards surrounded the cylinder with a solid brass ring, fastened to it by four projecting arms. The upper surface of the ring was on a level with the circle of black glass, which formed the surface of the top; and the inner curved surface of the ring was concentric with the outer curved surface of the top. In this form the top was sent out to the Arctic Regions with Captain Ross, but it did not give such satisfactory results as were expected. Mr. Troughton has since improved it, by giving it the form of an inverted frustum of a cone. The base or lower surface of the frustum is about 6 inches in diameter, the upper surface about 4 inches, and its height about $2\frac{1}{4}$ inches. The thickness of the metal which forms the cone is 1-8th of an inch. The reflecting plane which occupies the whole upper surface of the conical frustum, rests in a steel cup half an inch wide, and on a steel point which descends about half an inch below the upper surface of the frustum. The top is put in motion by an apparatus analogous to that used by Serson: but in place of a ribband, a series of wheels is used, the first and largest of which is put in motion by a winch or handle placed on its circumference. The velocity of the circumference of the base has been calculated at about 30 miles an hour.

Sect. III.—*Account of M. Ducom's Cylindrical Artificial Horizon.*

The instrument consists of two parts, one of which is a copper disk, six inches in diameter, with three feet. The second part is a cylindrical cover or drum, which performs the part of the glass roof in the common horizons for sheltering the fluid from the action of the wind. From the middle of the first part, or copper disk, there rises a hollow cylinder of white iron $4\frac{1}{2}$ inches high, and $2\frac{1}{2}$ inches in diameter. Upon this cylinder, which is open at top, there is placed a small round disk of white iron, (or of boxwood, where mercury is used,) which goes into the top of the cylinder, but is prevented from descending by a ledge on which it rests. This disk contains the mercury, wine, or prepared syrup, which is employed. These cylinders are adjusted in such a manner, that the surface of the fluid is exactly $2\frac{1}{2}$ inches above the first disk. On the copper disk are fixed two brackets, to which is fastened the cylindrical roof or drum. This drum, which is made of white iron, is six inches in diameter, and $2\frac{1}{2}$ wide, and is so placed that its centre is in the surface of the fluid in the round disk. In the middle of the width of the drum, there are two bands of white iron, perforated by two circular openings diametrically opposite to one another, and an inch in diameter, the one for letting in the incident rays, and the other for letting out the reflected ones. They have a circular motion by a rack and pinion on the surface of the drum, for the purpose of being adjusted to the height of the sun or the star.

When there is not much motion in the air, two small funnels, or truncated cones, are placed in the small tubes in the circular apertures, and these have the effect of protecting the fluid surface from every agitation. When the wind is considerable, the funnels are kept on, and a small glass with parallel faces is placed at the end, by which means the incident rays are admitted; but if the wind is very high, the funnels are taken off, and a piece of wire gauze is placed in the tube. This permits the external air to be in regular communication with the internal air, which is favourable to the accuracy of the observation.

Sect. IV.—*Description of the Level Sextant.*

Among the various contrivances for artificial horizons as applied to the sextant, one of the simplest is that shown in Fig. 16, which is a view of part of a sextant constructed by Mr. Troughton. A small level LL is fixed between the index glass E and the horizon glass D, and there is a hole in the side of the brass tube containing the level through which the bubble can be seen by the observer at E, by reflexion in the horizon glass, as shown in Fig. 17. where a line r is drawn across the glass where the contact is to be made, at the same time that the image of the bubble is to be bisected by the same line. This apparatus is said to have given the altitude within 5 minutes of the truth.

Sect. V.—*Description of Mr. M. Adam's Inverting Sextant Telescope, with Nautical Eye-Tube.*

" This telescope, represented by AB, Plate CCCCLXXXVII. Fig. 18, consists of three parts; viz. 1st, The eye-tube AE, to the lower side of which a spirit-level $k\,x$ is attached by the screws o, p, passing through the extremities C and D of the frame of the level tube; 2d, The object tube FB, which is attached to the sextant by the screw at y; and, 3d, The middle, or connecting tube EF, represented separately by GH, Fig. 19, of which the part EH enters the object tube, at F, and the part EG is screwed into the eye tube at E by means of the screw EK, and thus brings the small glass G into its proper place at b near the field of the telescope. The reduced diameter of the part GK permits the upper side $k\,l$ of the level tube to enter 1-8th of an inch within the lower side of the eye tube, and thus brings the bubble, seen directly through the eye glass at A, as near as possible to the field of the telescope. In the centre of the field two cross hairs of silk intersect each other at right angles, the one horizontal and the other vertical; and the point of their intersection is adjusted exactly into the line of vision through the telescope by means of the screw nails c, d, acting on the diaphragm, the edge of which, seen at e, is filed quite thin on the farther side, for the purpose of more easily admitting the direct light of a lamp through the aperture, $a\,b$, to illuminate the cross hairs at night. $h\,i$, $q\,r$, and $s\,t$, are rectangular apertures in the frame of the level tube, and $t\,v$ is a reflector placed below $s\,t$ to illuminate the spirits, and to show more distinctly the position of the bubble. The lines f and g are painted on the level tube at opposite extremities of the bubble, when it is in the middle; and, as the level is applied so that the line f is placed at the focal distance of the eye glass, the eye end of the bubble can be distinctly seen at f, and at 1-3d of an inch on either side of it. When, therefore, $k\,l$, the upper side of the level tube is adjusted parallel to AB, the line of vision through the telescope, if the eye end of the bubble be observed, and kept at f, the line of vision AB must then be truly horizontal, or parallel to the horizon. In order to take the altitudes at sea by a quadrant or sextant, furnished with this telescope and level, which may be made capable of distinguishing 10″, the observer should hold the sextant, as usual, in a vertical plane, passing through the celestial object whose altitude is required, the telescope being horizontal, and then bring the reflected image of the sun, moon or star, into the field by the motion of the index on the limb of the instrument, which, after some experience, he will generally be able to do upon the first or second trial. When the celestial object is thus brought into the field, and the near end of the bubble seen at f in the level tube, the observer should clamp the index on the limb, and, by means of the tangent screw, while the near end of the bubble is kept at f, bring the lower limb of the observed object to touch the horizontal hair passing through the centre of the field; the required altitude of the lower limb of that object, affected only by refraction, will then be found, as usual, on the limb of the sextant.

To enable the observer to keep the eye end of the bubble at f till the required contact is observed, a light mahogany rod, about $2\frac{1}{2}$ feet in length, attached to the sextant, and parallel to the telescope, is pressed against some fixed object on deck, which enables him gently to elevate or depress the telescope till the bubble is brought into the required position, and kept there as long as may be necessary. For this purpose, an iron staunchion, about six feet in length, should be made to screw, when required, into different parts of the deck near midship, with a sliding projection, about two or three inches in length, which may be fixed by a finger-screw at any required height, so as to afford a convenient prop, against which the sextant rod may be pressed by the observer when taking observations. To show the cross hairs, and the position of the bubble, when taking night observations, a small lamp, made for this purpose, is applied to the right side of the eye tube by means of a brass rod fixed to the lamp, which slides in a square socket, attached to the cylinder on the right of the holder of the telescope. The quantity of light thrown upon the bubble and cross hairs, is easily increased or diminished, by moving the lamp rod a little forward or backward in the socket. The same lamp, when detached, enables the observer to read off his observations.

The screw $o\,m$, acting through the near end C of the level frame, gives it its vertical adjustment; and the two screws at p, acting horizontally against each other through the farther end D, give it its lateral adjustment. The accuracy of the vertical adjustment may be examined by comparing meridian altitudes of a celestial object, taken by means of the level, with those taken at, or nearly at, the same time, by means of an artificial horizon. At sea, the accuracy of this adjustment may be examined by moving the index backwards off the limb, as many minutes as are equal to the dip of the horizon, and then observing whether the reflected horizon of the sea is brought up to the horizontal hair in the centre of the field, when the eye end of the bubble is at f in the level tube; if not, its distance $\pm$ from it is equal to the error of the vertical adjustment, which may either be corrected by the screw, or allowed for, like an index error of the sextant.

To examine the latter adjustment, screw the object tube FB firmly into the sextant holder of the telescope by means of the screw at y, or fix it steadily, by other means, in a horizontal position, which is easily determined by the vertical adjustment of the level. Move the united eye and middle tube a few degrees round in it to the right and left; and observe whether the bubble, formerly in the middle, now moves to either end of the level tube. If it does not, the lateral adjustment is already made. If it does, correct the observed motion by means of the adjusting screws at p. If this adjustment is not made, a slight deviation of the plane of the sextant from the vertical plane, which the observer cannot detect, when shut out from the horizon of the sea, may cause a considerable error in the observed altitude. To prevent this, let a plummet be suspended behind the plane of the sextant, which will readily detect any deviation of the instrument from the vertical plane.

If EH, the middle tube of the telescope, be moved forward or backward in the object tube FB, so as to place the object glass a little too near, or too far from the cross hairs in the centre of the field, the image of the observed object may thus be brought nearer to or farther from the eye than the intersection of these cross hairs, without causing any apparent indistinctness of the image. In this case, when the eye is slightly elevated or depressed, it will cause the contact of the image with the horizontal hair to appear either too close or too open, and may thereby cause an error of one or more minutes in the observation, according to the distance of the image on either side of the cross hairs.

To avoid this source of error, care must be taken to mark on the middle tube EH a line εζ, to which the middle tube should be moved, so that the image of a celestial object may be formed exactly at the cross hairs; for then, any elevation or depression of the eye will cause no sensible change of the apparent contact of the limb of the image with the horizontal hair. The proper distance of the object glass is a constant quantity for all celestial objects, but it varies with the distance of terrestrial objects. As considerable care and application are necessary, in order to acquire correctness and facility in the practice of this method of observation, it will be proper, when practicable, that the observer should accustom himself to take observations by this method on shore, before he proceeds to sea."

Sect. VI.—*Account of Dr. Brewster's Improvement upon the Nautical Eye Tube.*

In using the preceding very ingenious instrument, the eye sees, by direct vision, the contact of the sun with the horizontal wire, and by oblique vision the contact of the bubble with one or both of the marks on the level. This double and simultaneous observation is difficult to make; but independent of this difficulty, there is a property of vision, in virtue of which an object seen obliquely disappears, as if it had been completely annihilated.

On this and other grounds, says Dr. Brewster, Mr. Adam's eye tube has always appeared to me susceptible of improvement. The first idea of this kind which occurred to me is shown in Fig. 20, where the field of view, ABCD, is contracted, and consists of a perforation in the reflecting mirror. The parts are then adjusted, so that when the wire AB touches the sun, the bubble AMBN is concentric with the field of view ACBD. This approximation of the bubble to the observed limb of the sun is an obvious advantage; but as it is liable to the objection formerly stated against oblique vision, I thought of the method shown in Fig. 21. In this method I dispense entirely with a metallic reflector, and I form the image of the bubble by a plate of parallel glass PD, lying between the eye and the field CD, and inclined 45° to the axis of the tube. By this means the bubble EF may be brought in contact with the wire AB; and the parts are adjusted, so that the axis of the telescope is horizontal when the wire AB is in contact with the lower end of the bubble and the upper limb of the sun. The only objection to this construction is, that the glass plate PD reflects little light; but this may be completely remedied, by placing the darkening glass anterior to the field of view, or by throwing an additional light upon the bubble of the level.

SHADOWS, Coloured. See Optics.

SHAFTESBURY, First and Third Earl of. See Cooper, Anthony Ashley.

SHAFTESBURY, or Shaston, a borough and market town of England, in the county of Dorset, is agreeably situated on a very high hill, which commands extensive views in Dorsetshire, Somersetshire, and Wiltshire. The principal streets are built on the roads from Wincanton, Warminster, Salisbury, Blandford, and Sherbourne, forming as it were a star. The houses are generally built of stone quarried on the neighbouring eminences; but they have a poor appearance, and the streets are narrow and irregular. The most important public buildings are four churches, St. Peter's, Holy Trinity, St. James', and St. Rumbold; St. Peter's, distinguished by the elegance of its proportions, as well as by its ornaments, is defaced by modern alterations. Part of the high embattled wall which enclosed the park and the abbey church still remains. The town-hall is a handsome building supported on five arches. There are also here three meeting-houses for Presbyterians, Methodists, and Quakers. The water which supplies the town is brought from the adjoining parish of Gillingham on horses' backs. They have therefore in several houses vast reservoirs for holding rain water. Lately, however, very good water has been obtained at the depth of 125 feet.

The charitable establishments here are a free-school, alms-houses for 16 women and 10 men, and other three of great antiquity converted into a poors' house.

The only manufacture in Shaftesbury is that of silk buttons, which gives employment to about 1200 persons.

The government of the town is vested in a corporation, composed of a mayor, recorder, 12 aldermen, a bailiff, and common councilmen. It sends to parliament two members, elected by about 300 voters paying scot and lot.

The eminence to the west of the town, called Castle Green, is supposed to have been the site of a castle. A small mount on the brow of this hill has been regarded as a Roman work. Many Roman coins have been found in the town. Population in 1821, 583 houses, 634 families, 388 in trade, and 2903 inhabitants.

SHAGREEN, or Chagreen, is the name of a kind of grained leather made in Astracan by the Tartars and Armenians, and much prized for forming covers for cases, books, &c. It is a close and solid substance, covered over with papillæ or little roundish grains. The following method of preparing it is a brief abstract of the method described by Professor Pallas.

The hinder back piece of the hides of horses and asses is cut off immediately above the tail, in the form of a crescent. The only part that is useful is about a Russian ell and a half across the loins, and a short ell along the back. The skins thus cut are soaked for several days in pure water till the hair drops off. They are then extended, and the hair and epidermis removed with a scraper. After a second soaking the flesh side is similarly scraped, and the whole cleaned till nothing but the pure fibrous tissue remains. The skins thus prepared are stretched in a wet state on wooden frames, with the flesh side downwards, and over the upper side are scattered the hard, black, and smooth seeds of the *chenopodium album*, or *goose foot*. A piece of felt is then spread over them, and the seeds are trodden into the leather. The frames are then placed against a wall with the seedy sides next it, and in this way they are perfectly dried. When the unpressed seeds are beaten off, the skin is full of indentations, which produce the grain of the shagreen.

The dried skins are next scraped with a piece of sharp iron bent like a hook, till all the inequalities are removed, and this process is repeated with a finer scraper till only faint impressions of the seeds remain.

In this condition the skin is put into water for 24 hours, and the effect of this is to swell the faint impressions of the seed, and raise it above the surface acted upon by the scrapers, a considerable part of which has been removed. The depressed parts which have lost none of their substance being thus elevated, constitute the grain of the shagreen.

The skins are now immersed several times in a strong warm ley, obtained by boiling a strong alkaline earth called *schora*. They are then piled upon one another while warm, and in some hours they swell and become soft. They are afterwards rendered exceedingly white and beautiful by 24 hours immersion in a strong pickle of salt.

The next step in the process is to give the skins their final colour. The following is the method for the most common colour, which is sea-green. Let the skins, when taken from the pickle, have their flesh or unprepared sides well washed with a saturated solution of sal ammoniac. A thick layer of copper filings is then strewed over them. Each skin being rolled up in a piece of felt, the rolls are all laid together in proper order, and pressed down for 24 hours by some heavy body. During the time the sal ammoniac has dissolved a sufficient quantity of the coppery particles sufficient to give the skin a sea-green colour.

In order to give the *blue* colour, two pounds of finely powdered indigo are dissolved in cold water. Five pounds of pounded alakar, or crude soda, is then dissolved in it, along with 2 lbs. of lime and 1 lb. of pure honey. The whole is put several days in the sun and often stirred. The skins to be dyed blue are to be moistened only in the strong ley of schora, and not in the salt brine. When moist they are filled up and sewed together at the edge, the flat side being innermost, and they are dipped thrice in the remains of an exhausted kettle of the same dye, the superfluous dye being each time squeezed out, and after this process they are dipped in the fresh dye prepared as above, which must not be squeezed out. The skins when dried and pared are finished.

In order to make *black* shagreen, the skins when moist from the pickles are thickly bestrewed with pulverized gall nuts, and then folded together and laid over each other for twenty-four hours. Each skin is next dipped several times in a new ley of the *schora*, after which they are again bestrewed with rounded gall nuts, and placed in heaps till the galls have thoroughly penetrated them. When freed from the dust of the galls by beating, they are rubbed over on the shagreen side with melted sheep's tallow, and exposed to the sun to imbibe the grease. When the superfluous particles have been scoured by a blunt wooden scraper, and the skins have lain some time, the shagreen is moistened on both sides with a solution of sulphate of tin, by which it receives a beautiful black.

In order to make *white* shagreen, the skins are first moistened on the shagreen side with a strong solution of alum, and then daubed over on both sides with a paste made of flour. The paste, when dried, is washed off with alum water, and the skin is then dried in the sun. When the skins have imbibed sheep's tallow, as described in the last paragraph, the superfluous fat is scraped off with a blunt wooden instrument, when the skins are wet with warm water.

This white shagreen is intended for receiving a dark red colour. In this case the skins must not be immersed in the solution of *schora*, but after being whitened they are washed in the pickle of common salt for 24 hours. About a pound of the best dried *tschagann*, *(saloia iricoides,)* is now boiled a full hour in about four common paillfulls of water, which thus acquires a greenish hue. The herb being taken out, half a pound of pounded cochineal is put into the kettle, and the liquor boiled a full hour with frequent stirring. About 15 or 20 drachms of orchil is added, and after a little more boiling the kettle is removed. The skins taken from the pickle are then placed over each other in troughs, and the dye liquor is poured over them four times, and rubbed into them with the hands. The liquor is expressed each time, after which they are dried, and are much more valuable than any of the other kinds of shagreen.

Shagreen has sometimes been made of the skins of fishes, such as the angel fish, the greater dog fish, and the sea calf.

The best shagreen is that which is brought from Constantinople, which is of a brownish colour; the white is not esteemed good. Shagreen is frequently counterfeited by Morocco, but the counterfeit is distinguished by its peeling off, which the other never does. See M. B. Valentini *Museum Museorum*, &c. p. 439. Ray's *Synopsis*, *Mem. Quadr.* p. 63. Willoughby's *Ichthyol.* and Pallas's *Travels*. See also our article Astracan.

SHAINT, or Holy Isles, three small islands of the Hebrides, or Western Islands of Scotland, are situated in the Channel between the islands of Lewis and Sky, in the parish of Lochs, and county of Inverness. One of them called *IlUan Mouir*, or St. Mary's Island, has a small chapel upon it, dedicated to the Virgin Mary, and exhibits traces of having been more populous than at present. These islands are remarkable for their sheep and pasturage. For the purpose of breeding the cattle one family resides in a wretched hut. The mineral Wavellite was first found in Scotland on this island.

SHAKSPEARE, William, the celebrated father of the English drama, was born at Stratford-upon-Avon, on the 23d April 1564. About ten weeks after his birth the plague broke out in the town, but fortunately did not reach the house where he lay. He was the son of John Shakspeare, a considerable dealer in wool, and whose family "were of good figure and fashion." His mother was the daughter and heir of Robert Arden* of Wellingcote. He appears to have been bred for some time at a free school, where he is said to have acquired what Latin he was master of. Being designed to follow his father's profession, he left school to assist him in his business.

About the eighteenth year of his age young Shakspeare married Ann Hathaway, a lady eight years older than himself, and daughter of a substantial yeoman residing at Shottory, a hamlet to Stratford. By her he had three daughters, Susannah, baptized May 26, 1583, and Judith and Hannah, twins, who were born on the 2d February, 1584-5.

About this time our Poet, according to Rowe, fell into bad company, and aided his associates in carrying deer from the park of Sir Thomas Lucy of Charlcote, near Stratford. A prosecution was on this account raised against him, and carried on with such severity that he was obliged to fly from home, to avoid arrest and imprisonment.† On this account he went to London, where he had a relative and kinsman, Thomas Green, a "celebrated comedian." Here he seems to have accepted of a subordinate office in the theatre, and it is said that he was first engaged while the play was acting to hold the horses of those who had rode to the theatre.

From this humble occupation Shakspeare soon rose to that of an actor, as appears from some old plays in which his name is printed among those of the other players. We are not informed, however, of the parts which he acted; but it is said that the part which he performed best was that of Hamlet's ghost, and that he also played the character of Adam in *As You Like it*. There is reason to believe that he performed the part of Old Knowell in Ben Johnson's *Every Man in his Humour*, and Malone has concluded that he commonly played the parts of old men. So late as 1603, his name appears among the players of Ben Johnson's tragedy of Sejanus.

It is a remarkable circumstance that neither the name of his first play, nor the date of its publication is positively known: and the greatest uncertainty exists relative to the chronological order in which the whole series were composed, acted, or published.

We are indebted to Malone for the first attempt to assign to them the dates of their composition; but as our learned countryman, the late Mr. George Chalmers, has controverted some of his positions, we shall give a table and the dates affixed to the different plays by both these authors.

* According to John Aubrey, who was entered a student at Oxford in 1642, only 26 years after Shakspeare's death, and who says that he derived his information from some of his neighbours, "his father was a butcher, and when he was a boy he exercised his father's trade, but when he killed a calf he would do it in a high style, and make a speech."

† Shakspeare is said to have reflected upon Sir Thomas by writing a satirical ballad, which so exasperated the baronet, that he carried on the process against him with double eagerness, and forced him to quit Stratford. The first stanza of this ballad is said to have been preserved by tradition, and to have been as follows:

A Parliament Member—a Justice of Peace,
At home a poor Scarecrow—at London an asse.
If lowsie is Lucy as some folke miscall it,
Then Lucy is lowsie whatever befall it.
He thinks himself greate,
Yet an asse in his state,
We allow by his ears, but with asses to mate.
If Lucy is lowsie, as some folks will have it,
Sing lowsie Lucy whatever befall it.

‡ Malone is of opinion that the *First* Part of Henry VI. published in 1589, was not written by Shakspeare, though it might have been corrected by him.

Othello	1611	1614
The Tempest	1612	1613
Twelfth Night	1614	1613

Besides the preceding plays, *thirty-five* in number, Shakspeare wrote the following poetical pieces, which were published separately.

Venus and Adonis, printed in	1593
The Rape of Lucrece	1599
The Passionate Pilgrim	1599
A Lover's Complaint	without date
A Collection of Sonnets	1609

The first and second of these poems were dedicated, as the *first piece of my invention*, to Henry Wriothesley, Earl of Southampton, who, according to the statement of Sir William D'Avenant, presented Shakspeare with the sum of £1000 to make some purchases. Queen Elizabeth and King James I. seem also to have been well aware of the great talents of our dramatist. Queen Elizabeth frequently commanded his plays to be acted before her, and she was so much delighted with the character of Falstaff in the 1st and 2d parts of Henry IV. that she requested the poet to represent the fat Knight in love. In this way he was led to compose the *Merry Wives of Windsor*. King James likewise attended the performance of several of Shakspeare's plays, and, as Sir William D'Avenant informs us, Sheffield, Duke of Buckingham, wrote with his own hand *an amicable* letter to the poet.

At the commencement of the reign of this monarch, Shakspeare had become one of the principal managers of the playhouse, an office which he continued to fill for several years. As soon, however, as he had acquired a moderate fortune, he quitted the stage, and gave up all other employment, that he might spend the rest of his life in rural pursuits. He accordingly went to Stratford in 1612, where he had purchased a house called *New Place*, in which he spent the rest of his life as a private gentleman. The only event which disturbed the serenity of his latter days was the great fire at Stratford in 1614, which consumed the greater part of the town, and from which he had the good fortune to preserve his own residence.

In the beginning of the year 1616, Shakspeare seems to have anticipated his approaching dissolution. He then made his will,* and he died on the anniversary of his birthday, on the 23d April 1616. On the second day after his death he was intered among his ancestors on the north side of the chancel of Stratford church, where the monument erected to his memory still remains. It is partly of marble and partly of stone, and consists of a half length bust of the poet, with a cushion before him, placed under an ornamental canopy, between two columns of the Corinthian order, supporting an entablature on which is sculptured in bold relief the Shakspeare arms and crest. Beneath the bust are the following lines:—

Judicio Pylium, genio Socratem, arte Maronem,
Terra tegit, populus mœret, Olympus habet.

Stay passenger, why goest thov by so fast,
Read, if thou canst, whom enviovs death hath plast
Within this monvment, Shakspeare: with whome
Qvick natvre dide; whose name doth deck ys tombe
Far more than coste: sieh all yt he hath writt
Leaves living art, bvt page to serve his witt.
Obiit Anno Doi. 1616. *Ætatis* 53, *die* 23 *April.*

The following inscription, which tradition ascribes to Shakspeare himself, is on the flat stone which covers his grave:—

Good frend, for Jesus' sake forbeare,
To digg the dust encloased heare:
Blest be the man that spares these stones,
And curst be he that moves my bones

Malone is of opinon that this imprecation might

* In this will, which still exists in the prerogative court in London, and is dated March 25, 1616, Shakspeare made the following bequests:

To his daughter Judith he gave £150 of lawful money; £100 to be paid in discharge of her marriage portion, within one year after his decease, and the remaining fifty upon her giving up, in favour of her eldest sister, Susanna Hall, all her right in a copyhold tenement and appurtenances, parcel of the manor of Rowington. To the said Judith, he also bequeathed £150 more, if she or any of her issue, were living three years from the date of his will: but in the contrary event then he directed that £100 of the sum should be paid to his niece Elizabeth Hall, and the proceeds of the fifty to his sister, Joan, or Jane Hart, for life, with residue to her children. He further gave to the said Judith a broad silver gilt bowl.

To his sister Joan, besides the contingent bequest above mentioned, he gave twenty pounds, and all his wearing apparel; also the house in Stratford, in which she was to reside for her natural life, under the yearly rent of twelve pence. To her three sons, William Hart———Hart, and Michael Hart, he gave five pounds a-piece, to be paid one year after his decease. To his grand-daughter, Elizabeth Hall, he bequeathed all his plate, the silver bowl above excepted.

To the poor of Stratford he bequeathed ten pounds; to Mr Thomas Combe, his sword; to Thomas Russel five pounds; to Francis Collins, Esq. thirteen pounds, six shillings and eight pence; to Hamlet (Hamnet) Sadler, twenty-six shillings and eight pence, to buy a ring: and a like sum for the same purpose, to William Reynolds, gent., Anthony Nash, gent , John Hemynge, Richard Burbage, and Henry Cundell, his "fellows;" also twenty shillings in gold to his godson, William Walker.

To his daughter Susanna Hall, he bequeathed New-Place with its appurtenances; two messuages or tenements, with their appurtenances, situated in Henley-street; also all his barns, stables, orchards, gardens, lands, tenements, and hereditaments whatsoever, situate, lying, and being, or to be had, received, perceived, or taken within the towns, hamlets, villages, fields, and grounds of Stratford-upon-Avon, old Stratford, Bishopton, and Welcombe, or in any of them, in the said county of Warwick; also all that messuage or tenement, with the appartenance, wherein one John Robinson dwelleth, situated, lying, being in the Blackfriars, London, near the Wardrobe; and all my other lands, tenements, and hereditaments whatsoever: to have and to hold all and singular the said premises, with their appurtenances, unto the said Susanna Hall, for and during the term of her natural life; and after her decease, to the first son of her body lawfully issuing, and to the heirs-male of the body of the said first son, lawfally issuing: and for default of such issue, to the second son of her body lawfully issuing; and to the heir-male of the body of the said second son lawfully issuing; "and so forth, as to the third, fourth, fifth, sixth, and seventh sons of her body, and their heirs-male;" and for default of such issue, the said premises to be and remain to my said niece Hall, and the heirs-male of her body lawfully issuing; and for default of such issue, to my daughter Judith, and the heirs-male of her body lawfully issuing; and for default of such issue, to the right heirs of me the said William Shakspeare.

To the said Susanna Hall and her husband, whom he appointed executors of his will, under the direction of Francis Collins and Thomas Russel, Esqs he further bequeathed the whole of his "goods, chattles, leases, jewels, and household stuff whatsoever," after the payment of his debts, legacies, and funeral expenses, with the exception of his "second best bed with the furniture," which constituted the only bequest he made to his wife, and that by insertion after the will was written out.

have been suggested by the dread that his remains might some day or other "be added to the immense pile of human bones deposited in the charnel house at Stratford."

In the year 1740, a magnificent monument was erected at Westminster Abbey at the public expense, to the memory of Shakspeare. A very large sum for this purpose was obtained from the exhibition of the tragedy of Julius Cæsar at the Theatre-Royal, Drury Lane, on the 28th April 1738.

The first collection of the plays of Shakspeare was published in London in 1623, in folio, by Isaac Jaggard and Ed. Blount, under the title of "Mr. William Shakspeare's Comedies, Histories, and Tragedies." It was edited by John Hemynge and Henry Condell, and was dedicated to the Earl of Pembroke and the Earl of Montgomery. On the title page is an engraving of the poet by Martin Droeshout and on the opposite page are the following lines by Ben Jonson.

> This figure that thou here seest put,
> It was for gentle Shakspeare cut,
> Wherein the graver had a strife
> With nature to outdoo the life:
> O, could he but have drawn his wit
> As well in prose as he hath hit
> His face; the print would then surpasse
> All that was ever cut in brasse,
> But since he cannot, reader, looke
> Not on his picture, but his booke.

A second folio edition of Shakspeare was published in 1632, a third in 1664, and a fourth in 1685, and not many years ago, the first edition was reprinted in close imitation of the original, by Vernon and Hood, London.

In 1709 Nicolas Rowe published an edition in 7 vols. 8vo. to which was prefixed a biographical memoir of Shakspeare. Another edition, by the same editor, appeared in 1714 in 9 vols. 12mo.

In 1725 Pope published an edition in 6 vols. 4to. with critical and commendatory notes; and in 1725, the same editor published another edition in 10 vols. 12mo. with additional notes and corrections.

In 1733 Theobald brought out an elaborate edition in 7 vols. 8vo., and a second in 1740 in 8vo. with corrections and additions.

In 1744 Sir Thomas Hanmer published an edition in 6 vols. 4to.

In 1747 Warburton published his edition in 8 vols. 8vo.

In 1765 Dr. Johnson published an edition in 8 vols. 8vo. with an able preface on the character of Shakspeare's writings.

In 1766, Stevens published the *Old Plays* in 4 vols. 8vo.

In 1768, Mr. Capell published an edition in 10 vols. crown 8vo.

In 1771, Sir Thomas Hanmer published a second and improved edition in 6 vols. 4to.

In 1773 Jonhson and Purves published conjunctly an edition in 10 vols. 8vo. of which a second edition appeared in 1778, and a third in 1785, revised and corrected by Mr. Reed.

In 1786, Joseph Roan published the first volume of the Dramatic Works of Shakspeare, with notes. This work was completed in 6 vols. 8vo. in 1799.

In 1784, there was published by Stockdale an edition in 1 vol. royal 8vo. with a copious index of passages by the Rev. Mr. Ayscough.

In 1788, appeared Bell's edition in 20 vols. 12mo.

In 1770, Malone published his edition in 10 vols. crown 8vo.

In 1773, a fourth edition, revised and augmented, was published by Mr. Steevens in 15 vols. 8vo.

In 1803, there was published a fifth edition in 21 vols. 8vo. from the text, and with the notes of Johnson, Steevens, and Reed. Another edition of the work appeared in 1813.

In 1805, an edition was published in 10 vols. 8vo. with a prefatory essay by Alexander Chalmers, F. S. A. In this edition each play is illustrated with a print designed by Fuseli.

Besides these editions, a splendid one was published by Boydell in 9 vols. folio, embellished with 100 engravings, executed by the most eminent artists. A quarto edition of the work was also printed. An edition of Shakspeare, printed by Whittingham, has also been published in 1814, in 7 vols. 18mo. illustrated with 230 engravings on wood, with remarks on the life and writings of Shakspeare, by John Butters, F. S. A. It has been calculated that at least 100,000 copies of Shakspeare's works have been printed and sold.

The following excellent character of Shakspeare as a Dramatic Writer, has been drawn up by the able pen of Dr Johnson.

"Shakspeare is above all writers, at least above all modern writers, the poet of nature; the poet that holds up to his readers a faithful mirror of manners and of life. His characters are not modified by the customs of particular places, unpractised by the rest of the world; by the peculiar writers of studies or professions, which can operate but upon small numbers; or by the accidents of transient, factitious, or temporary opinions: they are the genuine progeny of common humanity, such as the world will always supply, and observation will always find. His persons act and speak by the influence of those general passions and principles by which all minds are agitated, and the whole system of life is continued in motion. In the writings of other poets a character is too often an individual; in those of Shakspeare it is commonly a species.

It is from this wide extension of design that so much instruction is derived. It is this which fills the plays of Shakspeare with practical axioms and domestic wisdom. It is said of Euripides, that every verse was a precept; and it may be said of Shakspeare, that from his works may be collected a system of civil and economical prudence. Yet his real power is not shown in the splendour of particular passages but by the progress of his fable, and the tenor of his dialogue; and he that tries to recommend him by select quotations, will succeed like the pedant in Hierocles, who, when he offered his house for sale, carried a brick in his pocket as a specimen.

Upon every other stage the universal agent is love, by whose power all good and evil is distributed, and every action quickened or retarded. But love is only one of many passions; and as it has no great influence upon the laws of life, it has little operations on the dramas of a poet who caught his ideas from the living world, and exhibited only what he saw before him. He knew that any other passion, as it was regular or exorbitant, was a cause of happiness or adversity.

Characters thus ample and general were not easily discriminated and preserved; yet perhaps no poet ever kept his personages more distinct from each other.

Other dramatists can only gain attention by hyperbolical or aggravated characters, by fabulous and unexampled excellence or depravity, as the writers of romances invigorated the reader by a giant and a dwarf; and he that should form his expectations of human affairs from the play or from the tale, would be equally deceived. Shakspeare has no heroes, his scenes are occupied only by men, who act and speak as the reader thinks that he should himself have spoken and acted on the same occasion: even where the agency is supernatural, the dialogue is level with life. Other writers disguise the most natural passions and most frequent incidents; so that he who contemplates them in the book will not know them in the world: Shakspeare approximates the remote, and familiarizes the wonderful. The event which he represents will not happen, but if it were possible, its effects would probably be such as he has assigned; and it may be said, that he has not only shown human nature as it acts in real exigence, but as it would be found in trials to which it cannot be exposed.

This, therefore, is the praise of Shakspeare, that his drama is the mirror of life; that he who has swayed his imagination in following the phantoms which other writers raise up before him, may here be cured of his delirious ecstacies by reading human sentiments in human language, by views from which a hermit may estimate the transactions of the world, and a confessor predict the progress of the passions."

Those who wish for farther information respecting the life and writings of Shakspeare, may consult, in addition to the works mentioned in the course of the preceding outline, the following:—*A Guide to Stratford-upon-Avon*, by R. B. Wheler, 1814, 12mo. *Critical, Historical, and Explanatory Notes on Shakspeare, with Emendations of the Text and Metre*, by Zachary Gray, L.L.D. 1755, 2 vols. 8vo. *Observations and Conjectures on some passages of Shakspeare*, by Thomas Tyrwhitt, Esq. 1764, 8vo. *An Essay on the Learning of Shakspeare*, by the Rev. Dr. Richard Farmer. Three editions of this work were published by the author himself, and it has been since frequently reprinted in different editions of Shakspeare. *An Essay on the Writings and Genius of Shakspeare, compared with the Greek and French Dramatic Poets, with some remarks on the Misrepresentations of M. de Voltaire*, by Mrs. Montague, 8vo. A sixth edition of the work appeared in 1810. *Essays on Shakspeare's Dramatic Character* by W. Richardson, M. D. 1812, 8vo. *Remarks, critical and illustrative, on the Text and Notes of the last edition of Shakspeare*, (1778), by Mr. Ritson, 1783, 8vo. *An Enquiry into the Authenticity of certain Miscellaneous Papers*, published Dec. 24, 1775, by Edmond Malone, Esq. 1796, 8vo. This volume gave rise to the two following works. *An Apology for the believers in the Shakspeare papers*, by George Chalmers, 1797, 8vo. *A Supplemental Apology for the believers, &c.* by the same Author, 1799, 8vo. *Illustrations of Shakspeare and of Ancient Manners*, by Francis Doucel, 1807, 2 vols. 8vo. and *Shaksperiana*, Lond. 1827.

SHAMMY, or Chamois, a soft and highly prized kind of leather, prepared from the skin of the Chamois, or *Antelope Rupicapra*, already fully described in our article Mazology.

An imitation of the shammy leather, by using sheep, goat, and kid skins, has been long successfully carried on about Orleans, Marseilles, and Thoulouse, and it there constitutes a particular profession under the name of *Chamoisure*. The following is the method employed :

Having washed and drained the skins, and strewed quick lime over the fleshy side, they are then folded in two lengthwise, the wool being outwards, and left to ferment 3 days, or 15 days, if they have been dried after flaying. When again washed out and drained, they are half dried, laid on a wooden horse, and the wool stripped off; they are then laid for 24 hours in a pit, in which the lime, from having been used before, had lost a great part of its strength. When taken out and allowed to drain 24 hours more, they are put into a pit with stronger lime, they are then taken out, drained, and put in again by turns, a process which is continued for six weeks in summer, or three months in winter, in order to dispose them to take oil. At the end of this period they are laid on the wooden horse, and are made softer by peeling off the surface of the skin on the wool side. Being now made into parcels, they are steeped a night in the river in summer, but longer in winter, and are then stretched six or seven above one another on the wooden horse, and the knife passed strongly over the flesh side, in order to remove any superfluous matter, and give smoothness to the skin. Then they are steeped, as before, in the river, and the same operation is repeated on the wool side; they are then thrown into a tub of water with bran in it, which is brewed among the skins till the greatest part stick to them, and then separated into distinct tubs till they swell and rise of themselves above the water. By this means the remains of the lime are cleared out: they are then wrung out, hung up to dry on ropes, and sent to the mill with the quantity of oil necessary to scour them: the best oil is that of stock fish. Here they are first thrown in bundles into the river for twelve hours, then laid in the mill trough, and fulled without oil till they be well softened; then oiled with the hand one by one, and thus formed into parcels each, which are milled and dried on cords a second time; then a third, and then oiled again and dried. This process is repeated as often as necessity requires; when done, if there be any moisture remaining, they are dried in a stove and made up into parcels wrapt up in wool: after some time they are opened to the air, but wrapped up again as before, till such time as the oil seems to have lost all its force, which it ordinarily does in 24 hours. The skins are then returned from the mill to the chamoiseer to be scoured; which is done by putting them in a lixivium of wood ashes, working and beating them in it with poles, and leaving them to steep till the ley has had its effect, then they are wrung out, steeped in another lixivium, wrung again: and this is repeated till all the grease and oil be expelled. When this is done, they are half dried and passed over a sharp edged iron instrument placed perpendicular in a block which opens, softens, and makes them delicate. Lastly they are thoroughly dried and passed over the same again;

which finishes the preparations, and leaves them in the form of shammy.

In the same manner kid and goat skins are shammoised, excepting that the hair is taken off without the use of any lime; and that when brought from the mill they undergo a particular preparation called *ramalling*, which is the most delicate and difficult of all. It consists in this that as soon as the skins are brought from the mill, they are steeped in a pit lixivium, taken out, stretched on a wooden leg, and the hair is scraped off with the knife. This makes them smooth and causes them in working to cast a kind of fine knap. The great difficulty of this process is to scrape the skin with sufficient evenness.

SHARK, see ICHTHYOLOGY.

SHARPE, James, Archbishop of St. Andrews, was born in 1618, and was descended from a respectable family in the county of Banff. Being intended for the church, he was educated at the university of Aberdeen. In 1638, when the solemn league and covenant was formed, he united with several of the learned men of the university in opposing it, and from the unpopularity which this cast upon him he retired to England.

The commencement of the civil wars induced him to return to his native county, where through the influence of Lord Oxenford and Lord Kelly, who was delighted with his conversation, he obtained a professorship in the university of St. Andrews. The Earl of Crawford soon afterwards gave him the church of Crail, where he performed the functions of the ministry in an exemplary manner.

Attached to the name of royalty, Mr. Sharpe had for some time maintained a correspondence with the king, and on the death of the pretender, he had frequent communication with General Monk. Previous to the restoration, the presbyterians sent Mr. Sharpe to London, in order to support their cause, and at the request of General Monk and the principal Scottish presbyterians, he was sent over to the king at Breda, in order to prevail upon him to establish presbyterianism in Scotland. Upon his return from this mission he declared to his constituents that "he had found the king very affectionate to Scotland, and resolved not to wrong the settled government of the church: but he apprehended they were mistaken who were about to establish the presbyterian government."

After the unconditional restoration of Charles, both he and his ministers resolved upon the re-establishment of prelacy, and Mr. Sharpe was prevailed upon to abandon the cause of his constituents, by the bribe of the Archbishoprick of St. Andrews.

Thus convicted of perfidy by his own acts, the name of the archbishop became odious throughout Scotland. Many of the wanton cruelties which were afterwards perpetrated, were ascribed to his influence; and it is at least certain, that after the battle of Pentland, when he had received an order from the king to stop the execution, he kept it in his possession for some time before he gave it to the criminal.

The object of such general detestation as the archbishop had now become was not likely to escape from popular vengeance. One Mitchell, a preacher, and an ardent zealot, resolved to assassinate him. He fired a pistol at him while sitting in his coach in Edinburgh, but the bishop of Orkney raising his hand at the instant interrupted the ball. The assassin walked leisurely home, and, throwing off his disguise, again mixed with the crowd.

Some years afterwards the archbishop observed a person looking at him with unusual sternness, and suspecting his design, ordered him into custody. Two loaded pistols were found upon him, and, upon examination, it proved to be Mitchell. A pardon was offered to him by the primate if he would confess his crime. Mitchell complied with the request, but heedless of his promise, the archbishop carried him before the council. A promise of pardon was again offered him by the council if he would discover his accomplices. This he also did, but it appeared that only one man, who had died since, was acquainted with his intentions.

The culprit was next brought before a court of justice and being commanded to make a third confession he declined. After suffering imprisonment for several years he was again tried, and convicted by his own confession. He urged in his defence the illegality of the evidence, and the promise of pardon which had been twice made to him: but the council having taken an oath that they had given no such promise Mitchell was condemned and executed.

This unprincipled transaction, which was carried through by the influence of the primate, was destined to meet with speedy punishment. In the year 1779, one Carmichael, a servant of the archbishop, having made himself odious to the presbyterians, nine men entered into a plan of waylaying him in Magus muir, about three miles from St. Andrews. While they were laying in ambush for the servant, the primate himself appeared with very few attendants. This was considered as a declaration of heaven in their favour, and calling out "The Lord has delivered him into our hands," they ran up to the carriage, and fired at him without effect. They then tore him from his carriage, and despatched him with their swords, regardless of the tears and supplications of his daughter by whom he was attended. Although this murder, for which no apology can be made, was entirely unpremeditated, yet the whole body of the presbyterians was accused of being parties to the crime, and several individuals who were entirely innocent, suffered death, as the perpetrators of the deed.

SHARP, Abraham, a celebrated English mathematician and astronomer, was born in 1651, at Little Norton, near Bradford. Having been apprenticed to a merchant in Manchester, he devoted all his leisure to mathematics, and acquired such a passion for them, that, with the consent of his master, he abandoned his profession, and went to Liverpool to pursue his mathematical studies.

Having heard of Sharp's mathematical acquirements, a London merchant, in whose house the celebrated astronomer Flamstead resided, engaged him to keep his books. In this situation our author acquired the friendship of Flamstead, through whose influence he obtained a lucrative situation in the dock-yard at Chatham. Mr. Sharp's talents, however, were of too high an order to be thrown away upon such an occupation, and Mr. Flamstead accordingly took him as his own assistant. Having a great mechanical genius, he was employed in the construction of the mural sextant, 6½ feet radius, which he finished in 1689, in the course of 14 months, to the entire satisfaction of Mr. Flamstead. See our article GRADUATION.

While in this situation Mr. Sharp assisted the astronomer royal in writing the celebrated catalogue of 3000 fixed stars; but owing to the fatigue of nightly observation, and to the weak state of his constitution, his health was greatly impaired, and he retired to his house at Norton.

When he had sufficiently recovered from his indisposition, he fitted up an observatory of his own, and furnished it with telescopes, the lenses of which he ground and adjusted with his own hand.

Our author likewise assisted Flamstead in computing most of the tables in the second volume of the *Historia Celestis*, and he executed fine drawings of the constellations which were sent to Amsterdam to be engraved, but though done by the hand of a master, the originals are said to have far exceeded them in minuteness and beauty.

In the year 1717, Mr. Sharp published a work entitled *Geometry Improved*, illustrated with a variety of copperplates, neatly engraved by his own hands. This work contained, 1. A large table of segments of circles, with the method of its construction and its uses in the solution of various different problems, and 2. A concise treatise of Polyedra or solid bodies of many bases.

Mr. Sharp was never married, he spent his life in a recluse manner, and exhibited many singularities which it would be out of place here to record. He died on the 18th of July 1742, in the 91st year of his age. See the *General Biography*, and Hutton's *Dictionary*, for farther information.

SHARPE, GRANVILLE, celebrated for his unwearied exertions in the great cause of the abolition of the slave trade, was born in 1734, and was the son of Mark Sharpe, Archdeacon of Northumberland, and the grandson of John Sharpe, archbishop of York. He was educated for the bar, but he did not follow the law as a profession. He was the author of some works of little importance. He died in July 1803, in the 79th year of his age. On the 6th July 1826 a bust of him by Chantry was placed in the Council Room at Guildhall, with the following inscription:—

GRANVILLE SHARPE,
to whom
England owes the glorious verdict of her
highest Court of Law,
that
the Slave who sets his foot on
British ground
becomes at that moment
FREE.

The details of his life will be found in the *Monthly* and *Gentleman's Magazine* the *Edinburgh Review*, vol. xii. Clarkson's *History of the Abolition of the Slave Trade*, and Rees' *Cyclopædia*, ART. SHARPE.

SHAT-el-ARAB, or CHAT-el-ARAB, Arabic name of the Euphrates and Tigris below their junction. As delineated in our modern maps, these two rivers form their main junction at N. lat. 31° nearly, and about long. 47° E. from London. In a country of moving sands and flat surface, and on which the efforts of human labour have been often exerted in the lapse of perhaps 40 centuries, great changes must have taken place. Pliny as quoted by Malte Brun, supposed the Euphrates to have once entered the Persian Gulf without receiving the Tigris and Ahwas. This opinion Niebuhr has revived, but the probability is that similar to the Mississippi and Red river in the United States, and the Ganges and Burrampooter in Asia, that the Euphrates and Tigris having one common recipient, always mingled their waters, though extensive revolutions may have taken place in partial channels. In their actual state, the Euphrates and Tigris unite as already stated. The union is made below Korna, where the stream turns to north-east a few miles, and receiving the Gyndes or Ahwas from the north, turns to SE., passes Bassorah, and after a course of about 100 miles falls by three principal and several smaller mouths into the Persian Gulf. The southern channel is the deepest, but shifting sands render the entrance of this great river dangerous. The tide ascends the Shat-el-Arab into the Euphrates and Tigris.

DARBY.

SHAW, GEORGE, an eminent British naturalist, was born at Bieston in Buckinghamshire, where his father was vicar, on the 16th December 1751. In 1765 he entered Magdalene Hall, Oxford, and in 1772 he took his degree of M. A. Although he was ordained deacon in 1774, and performed his duties regularly at two chapels, yet he quitted the clerical profession, and went to Edinburgh, where he studied medicine for three years. Upon his return to Oxford, he was appointed by Dr. Sibthorp, deputy botanical lecturer, and on the death of that gentleman he would have succeeded to the chair, had it not been a law that no person in holy orders could be elected. After taking his degree of bachelor and doctor of medicine, in 1787 he went to London to practise as a physician. On the establishment of the Linnean Society, he was made one of the vice-presidents, and he afterwards contributed various papers to its transactions.

In 1789, Dr. Shaw began the Naturalist's Miscellany, a monthly publication, which he continued to superintend till his death. In the same year he was elected a fellow of the Royal Society of London, and in 1791 he was appointed deputy-keeper of natural history in the British Museum.

Between the year 1792 and 1796, he published the different parts of a work, entitled *Musæi Leveriani Explicatio Anglica et Latina opera et studio Georgii Shaw, M. D. F. R. S. Adduntur figuræ eleganter sculptæ et colorotæ. Impensis Jacobi Parkinson.* He also published in "the Zoology of New Holland," and a work entitled "Cimelia Physica," "Descriptions of the Quadrupeds, Birds, &c." of which Miller had published the drawings in 60 large plates.

In the year 1800, Dr. Shaw began his principal work, entitled "General Zoology, or Natural History, with plates from the best authorities, and most select specimens." Of this work nine volumes were published in the author's lifetime, and the ninth was left ready for publication.

In 1807, Dr. Shaw published in two vols. 8vo. a course of Zoological Lectures which he had delivered in 1806 and 1807. Upon the death of Dr. Gray in 1807, he was promoted to the situation of keeper of natural history in the British Museum, an office which he filled till his death. When Dr. Hutton and Dr. Pearson projected, in 1809, an abridgment of the *Philosophical Transactions*, Dr. Shaw undertook the department of natural history. In the discharge of this duty he abridged 1500 distinct articles, in which he inserted the Linnean and specific names with occasional annotations and frequent references. This was the last separate work in which our author was engaged. An illness, which lasted but for a few days, carried him off on the 22d July 1813, in the 62d year of his age. See the *Gentleman's Magazine*, 1813, p. 290, and our article Mazology.

SHAWL GOAT, is the name given to the goat of Thibet, which is merely a variety of the common goat. Its wool, however, is celebrated for its excellent quality, being the material from which the fine Indian shawls are manufactured. As some attempts, though unsuccessful, have been made to introduce them in Scotland, our readers will naturally expect some information on the object.

The animal has a large head, long and slightly bent horns, which lie backwards, and a straight back, with delicate limbs. The coat consists of a thick external covering of long coarse hair, which conceals the fine wool, which is curled up close to the skin; the fleeces are shorn with a knife about the end of spring, they are then sorted according to the colour and quality. The long hairs are all picked by the hand from the wool; the wool is then washed in a warm and weak solution of pot ashes, and afterwards in water; it is then bleached on the grass, carded and prepared for spinning. The wool to be dyed receives its colour before carding: It is then dyed a second time before spinning, and once more when manufactured into the shawl. In Tartary it is spun by the hand with the distaff and spindle, and great care is taken not to spin the thread too hard, as the softness of the shawl depends upon this being properly done. A superfine shawl requires 5lbs. of wool, a shawl of the second quality requires 3 lbs., and one of inferior quality 2lbs.

An attempt was made some years ago to imitate the Indian shawls in this country. For this purpose some bales of shawl wool were imported, but the Norwich manufacturers could not spin it so as to produce a thread of equal fineness and quality with that from the merino lamb's wool, though the staple was at least five times as long. Mr. Main of Bow Lane, however, contrived machinery by which he produced threads superior even to those of Thibet manufacture.

The Duke of Athol made two attempts, one in 1815, and a second in 1816, to naturalize the shawl goat at Blair and Dunkeld in Scotland. Mr. Dunlop of Balnakeil in Sutherland, made another attempt in 1817. His flock was entirely black. It prospered for two years, and was purchased by some persons in France.

Mr. Macpherson Grant of Ballindalloch made another experiment in 1816, but the result of this does not seem to have been more favourable than those which have already been mentioned.

A more detailed account of these attempts will be found in a paper by Dr. Macculloch, in Brande's *Journal*, vol. ix. p. 330.

SHEEP, See Agriculture, Index, and our Article Mazology.

SHEERNESS, a sea-port and market town of England, on the Isle of Sheppey and county of Kent, is situated at the mouth of the River Medway.

In order to defend the entrance of this river, a fort was erected at Sheerness in the time of Charles II. In 1667 the works were greatly strengthened, but the Dutch having sent a fleet to the port in 1668, destroyed the fortifications, and having sailed up the Medway as high as Upnor Castle, did considerable damage to the shipping. This hostile enterprize induced the government to erect a regular fortress, and to mount it with a line of large and heavy cannon. Several smaller forts were built at the same time at different parts on the banks of the river, and since that time Sheerness has been progressively strengthened by new works, and now constitutes a regular garrison, commanded by a governor, lieutenant-governor, and fort-major. Adjacent to the fort is the king's yard or dock for repairing vessels, and for building frigates and smaller ships from 40 guns downwards. The chapel is a modern building erected by government for the use of the garrison, but all marriages and burials are performed at Minster.

A number of old line of battle ships have, for a considerable time, been stationed as breakwaters. They are inhabited by about 80 families, and present a very singular aspect to the stranger, from the chimnies being raised 38 feet of brick from the lower gun decks.

The chief supply of water having been brought in vessels from Chatham, the garrison and the inhabitants were often put to great inconvenience from the scarcity of that necessary article. It was resolved, therefore, by the Board of Ordnance in 1781, to sink a well within the fort. After digging to the depth of 328 feet, the auger with which they were boring dropped down, and the water rushed up with such velocity that the workmen could scarcely be drawn up in time to save them from being drowned. In six hours it rose 189 feet, and in a few days it rested within 8 feet of the top. The supply since that time has never failed. The water is of a pure and soft quality, and its temperature is somewhat higher than that of other wells. Population in 1821, 817, a decrease having taken place from the reduction in docking and ordnance establishment. See Hasted's *History of Kent*, the *Beauties of England and Wales*, vol. vii. and our article Kent.

SHEFFIELD, a large manufacturing town of England in Yorkshire, is situated on an eminence at the confluence of the Sheaff and Don, each of which is crossed by a stone bridge, that of the former consisting of one arch, and the other, called Lady bridge, with six arches. Sheffield extends about a mile in length from north to south, and nearly as much in breadth from east to west. It occupies principally an oblong hill, but it stretches over the adjoining valleys, and again ascends the hills at each end. In the old part of the town, the streets are narrow, but they are in general regular, running in a direct line, and containing many respectable, handsome, and uniformly built houses.

The principal public buildings are the town hall, the cutlers' hall, the general infirmary, the barracks, the assembly rooms and theatre, three churches and a chapel, and seven dissenting meeting-houses, besides a unitarian church, and one for methodists, one for quakers, and one for Roman catholics. The town hall is a handsome new edifice built of stone, and stands in Castle Street near the fish market place. The cutlers' hall, built in 1776, stands on the south side of St. Peter's church-yard. The general infirmary begun in 1793, is a splendid, large, and commodious building, built of fine white freestone. It stands about half a mile to the west of the town. It was finished in a few years from poors' funds derived from subscriptions and legacies. The situation is very healthy, and the establishment is in every respect on the very best footing. Near the banks of the Don, on the north east of the town, are the military barracks, which were built about the same time as the infirmary. The building forms a very handsome pile, with an esplanade in front. The assembly room and theatre are contained in an elegant building in Norfolk Street, on the south side of the town. They were first created in 1762, but they were taken down and rebuilt on a greater scale. The churches are St. Peter's, or Trinity church, St. Paul's, and St. James's, and the chapel of the Duke of Norfolk's hospital. St. Peter's, which is the parish church, stands near the centre of the town, and is a gothic building with a spire. The Shrewsbury chapel, containing a monument of the earl of Shrewsbury, is on the south side of the chancel. At the entrance to the same division of the church is interred William Walker of Darnel, who is said to have been the executioner of Charles I., but who is supposed by Mr. Hunter to have been the translator of the *Vindiciæ contra Tyrannos.* St. Paul's is a handsome Greek building, finished only in 1771, though begun in 1720. St. James's Church, built by subscription, was finished only about 1790. The chapel of the Duke of Norfolk's Hospital is very large, and of an octagonal form. It was opened in 1777. The hospital itself, which stands on the eastern side of the Sheaff, was founded in 1670, by Henry, Earl of Norwich, but was more amply endowed in 1770 by Edward Duke of Norfolk. It consists of two quadrangles, each containing eighteen dwellings for the accommodation of eighteen men, and as many women, each of whom receives five shillings a-week, with clothing and coals. There is also another hospital for poor cutlers, founded in 1703, by Mr. Thomas Hollis of London; a free grammar school, erected in 1649; a writing school for poor boys, and two charity schools, one for boys, and another for girls. There are likewise in Sheffield two schools, one on Bell's and the other on Lancaster's plan. In the first, 450 boys and 350 girls are taught, and in the second 700 boys, and 600 girls.

A large market-place, with convenient shambles, was completed in 1786. Among the new buildings in Sheffield, may be enumerated the works of the Sheffield Gas Light Company, erected in 1819, near Sheaff Bridge; and in the vicinity, the warehouse, basin, and wharf of the new canal from Tinsley, opened in 1819.

This town has been long celebrated for its manufactures, for carrying on which it is particularly adapted, both from its situation on a navigable river, and from the abundance of coal, iron-stone, and lead in its vicinity. The hardware manufactures of Sheffield constitute the great source of its wealth. They consist of cutlery, and plated goods, the former comprehending the trades of making edge tools, joiner's tools, files, fenders, anvils, knives and forks, penknives, pocketknives, razors, scissors, snuffers, saws, scythes, hay and straw knives, sickles, sheers, awl-blades, bellows, nails, hafts, inkstands, buttons, cases, combs, together with the refining of steel. Under the head of plated goods, are comprehended candlesticks, tea-urns, coffee pots, saucepans, tankards, cups, and various articles of table furniture. Lenses and optical instruments are also manufactured here; and there are in the town and its vicinity, extensive foundries for iron, brass, and white metal.

Since the year 1297, Sheffield seems to have been the staple for iron manufactures; but for several centuries its trade was very limited, and consisted chiefly of the manufacture of sheath knives, scissors, scythes, and sickles. Early in the sixteenth century, iron tobacco boxes, and Jews' harps were manufactured; and in 1625, the master manufacturers were incorporated by the title of "The Company of Cutlers of Hallamshire," which is the only corporate body in Sheffield. Previous to 1750, the manufactures had not extended beyond Great Britain; but in that year, Mr. Broadbent opened a direct trade with the continent, which was greatly facilitated by the opening of the river Don in 1751, and within three miles of the town. The silver plating of brass and copper articles was now begun by Mr. Bolsover; and in 1758, the silver plated manufacture was set on foot by Mr. Hancock, on the most extensive scale. The wealth and population of the town increased with great rapidity, and have advanced with progressive steps, till Sheffield obtained its present elevated condition among the trading manufacturing towns in Britain.

During the civil wars, Sheffield was defended by a castle; but upon its surrender to the parliamentary army, it was demolished.

The scenery in the neighbourhood of Sheffield is of a variegated and romantic character. The ruins of Sheffield manor-house, the ancient seat of the Earls of Shrewsbury, and the place of Cardinal Wolsey's residence, a short time before his death, is situated about $1\frac{1}{2}$ mile to the east of the town. Wharncliffe park, the seat of J. A. Stuart Wortley, now Lord Wharncliffe, stands on the Don, about six miles to the north-west of the town. It is remarkable for the elegance of the mansion house, and the beauty of its grounds. The view of Sheffield, from the height over which it is entered from Wakefield, is very fine. There are some alum mines in the neighbourhood, and in the vicinity of the town is a quarry which yields excellent grindstones for cutlery.

Population in	1801	31,314	Increase.
	1811	35,840	4526.
	1821	42,157	6317.

See Aitken's *Description of the Country round Manchester*, 1795, *and the Beauties of England and Wales*, vol. xvi.

SHELBY, county of the United States in Ohio, bounded N. by Allen, E. by Logan, S. by Miami, SW. by Darke, and N. W. by Mercer: it is about equal to a square of twenty miles, or comprises an area of 400 square miles. This county is watered by the sources of Great Miami River. Population, 1820, 2,106. Seat of justice Sydney. Central Lat. 40° 20′ N., Long. W. from Washington City 7° 12′.

SHELBY, county of the United States in Kentucky, bounded N. by Henry county, E. by Franklin, S. by Salt river or Nelson, SW. by Bullitt, and by Jefferson W. Length 26, mean width 20, and area 520 square miles. The surface of this county is broken, with a productive soil, drained by the extreme northern branches of Salt river. Seat of justice Shelbyville. The centre of the county is at N. Lat. 38° 12′, Long. W. from Washington City 8° 07′. Population, 1820, 21,047.

SHELBY, county of Tennessee, occupying the south-west angle of the state, having Hardeman county E. and Madison N, the Mississippi river W. and the state of Mississippi south. Length 34, width 30, and area 1,020 square miles. This large county is yet but thinly inhabited, having by the census of 1820, 354 inhabitants, or only one to near three square miles. The western border, along the left bank of the Mississippi river, is in part composed of flat overflowed, though very productive soil. That particular feature called Bluffs here reach the margin of the Mississippi, at the mouth of Wolf river, where formerly stood Fort Pickering, now the village of Memphis. These Bluffs have from the Mississippi the aspect of hills, but are, however, only the western termination of the general level of the interior country, and are really parts of an immense buttress, reaching from Baton Rouge to near the mouth of Ohio. Wolf and Loosahatchie rivers rise in Hardeman, enter and traverse Shelby county, and unite immediately above their common influx into the Mississippi at Memphis.

The 13th degree of Long. W. from Washington City, and N. Lat. 35° 10′, unite in the western part of this county. The climate is here considerably within the limit of cotton cultivation, which with Indian corn are the principal objects of farming. Seat of justice Raleigh.

SHELBY, county of the United States in Indiana, on the waters of the Blue river branch of White river, having Rush county E., Decatur SE., Bartholomew S., Johnson W., Marion NW., and Madison N. Length from north to south 24, breadth 18, and area, 432 square miles. Shelbyville, the seat of justice and principal post office, stands on Blue river, 25 miles SE. from Indianopolis, N. Lat. 39° 31′, and Long. W. from Washington City 8° 40′.

SHELBY, county of the United States in Alabama, having the Coosa river E., Bibb county S., Tuscaloosa SW., Jefferson NW., and St. Clair N. Length 40, breadth 36, and area 1440 square miles. Population, 1820, 2416. Chief village or seat of justice Shelbyville. Central Lat. 33° 17′ N., Long., Washington City, 9° 42′ W.

SHELBY, county of the United States in the central part of the state of Illinois, boundaries not known to the writer. By the post office Register, the seat of justice, Shelbyville, is 35 miles from Vandalia, the seat of government for the state.

SHENANDOAH, river of the United States in Virginia, rising at N. Lat. 37° 56′, in the extreme southern angle of Augusta county. The various sources, however, spread over, and drain the far greater part of Augusta and Rockingham counties. In the latter rises also a large though secondary branch, the North-Fork. Both streams issue separately from Rockingham, and flowing nearly parallel to each other, in a north-east direction, over Shenandoah county, the North Fork inflects to the east and joins the main stream near the south-east border of Frederick county. At their junction the Shenandoah has flown by comparative courses about 90, and the North Fork 60 miles. Now a fine mountain river, the Shenandoah, continues its direction to the north-east 40 miles, over Frederick and Jefferson counties, to its final influx into the Potomac, at Harper's Ferry, 39° 18′ N., having traversed 82′ of latitude. The level of Shenandoah and Potomac, at Harper's Ferry, is 182 feet above tide water in the latter: and comparing the sources of the former with those of James river, the elevation of their dividing ground must be at least 2,000 feet above the Atlantic tides: therefore, in a course of 82 minutes of latitude, the Shenandoah falls upwards of eighteen hundred feet.

This river and its branches flow from the fine valley between the Blue Ridge and Kittatinny mountain; the sources of the main stream in its entire course draining the north-west slopes of the former mountain. The Shenandoah valley in particular, comprises an area of very nearly 2500 square miles, and by the census of 1820, it then sustained a population of nearly 80,000 inhabitants, or 32 to the square; exceeding the general distributive population of Virginia 16 to 9. Occupying a part of the great limestone region stretching along the northwest base of the Blue Ridge, the Shenandoah valley is a grain and fruit producing country, and in a state of very rapid improvement. The climate it must be evident from its northern slope, is, in respect to temperature, inverse to the latitude. The sources in Augusta, elevated 1800 feet above the mouth, must influence the temperature equal to at least 4 degrees of latitude. Rising therefore from Harper's Ferry, though the advance is southward and length of the valley only 82 minutes of latitude, the seasons of spring, harvest, and autumn, and even winter, evince a change from a milder to a colder temperature, amounting to an equivalent to 2½ or 3 degrees of latitude.

SHENANDOAH, county of the United States in Virginia, and most correctly named, as it is in all its extent drained by the confluents and main stream of the river of the same name. This county stretches across the valley between the Blue Ridge and Kittatinny mountain, about 30 miles wide, with a length of 36 miles down the valley in a similar direction with the mountains and streams. Area 1080 square miles. The surface is generally mountainous or hilly, though considerable tracts of very productive soil skirt the streams. The population, in 1820, being 18,925, or nearly 19 to the square mile, evinces the existence of arable land of good quality. Central Lat. 38° 47′, Long. W. from Washington City, 1° 30′.

Darby.

SHELLS, See Conchology.

SHENSTONE, William, an English poet of some celebrity, and the eldest son of a country gentleman, who farmed his own estate, called the Leasowes, was born at Hales Owen in Shropshire, in November

1719. He received the first elements of instruction from the village "schoolmistress," whom he has made the subject of a poem under that title; and such was his ardour for reading when he was a child, that a new book was always brought to him by any member of the family that went to market. When that happened to be neglected, his mother was obliged to pacify him for the night, by wrapping up a piece of wood of the same form. At the grammar school of Hales Owen, he acquired the elements of a classical education; but he was afterwards placed under the charge of Mr. Crumpton at Solihues, who greatly improved his taste, and extended his classical acquirements. In 1732, he entered Pembroke College, Oxford, where his poetical genius first showed itself in some composition of considerable merit. With the view of taking a degree, he continued his name there for ten years; but having, in consequence of the death of his father in 1724, come into early possession of his estate, he did not professionally wear the civilian's gown which he had merely put on.

Content with his small patrimony, his talents were never called into vigorous action, and he was therefore led to devote himself to the enjoyment of domestic life, and to the pleasures of cultivating his mind, and of embellishing his grounds.

In 1737, he published anonymously a small volume of miscellaneous juvenile poems, but it did not excite much notice. His next work was the Judgment of Hercules, dedicated to Lord Lyttelton, which was published by Dodsley in 1740. This was followed, in 1742, by "The Schoolmistress," already alluded to, which is thought the best of all his productions.

From his friend, Mr. Graves of Mickleton, in Glocestershire, Shenstone is said to have derived his passion for rural embellishments, which he carried on without any regard to his pecuniary means. The Leasowes, which he thus extravagantly adorned, obtained great celebrity; and as it became a place of interest and public resort, he was involved in expenses, which held him under the constant pressure of poverty. His hospitality, or more properly speaking, his bounty, created wants which he could not supply; and tormented with the desire of doing more, and appearing better than he really could, he became the wretched tenant of the paradise which his own taste had created. The following account of Shenstone is from the pen of Gray,—"Poor man! he was always writing for money, for fame, and for other distinctions; and his whole philosophy consisted in living, against his will, in retirement, and in a place which his taste had adorned, but which he enjoyed only when people of note came to see and commend it. His anxiety of mind, which sprung out of his pecuniary necessities, seems to have thrown him into ill health; and though application was most properly made to Lord Bute to procure him a pension from the privy purse, yet, before this was granted, he was carried off by a putrid fever, in February 11, 1763, and was buried by the side of his brother in the church-yard of Hales Owen.

The "Works" of Shenstone "in Verse and Prose," were published in 1764, in 2 vols. 8vo., and a third volume, consisting of letters, appeared in 1769. Shenstone was a poet possessed of taste and a cultivated mind, but his works exhibit none of the *mens divina* which characterize the productions of true poetical genius. His prose writings contain acute remarks and just observations, and have the same general character as his poetical labours.

SHEPPEY, Isle of, an island of England in the county of Kent, is situated near the mouth of the Thames, and is separated from the mainland by a narrow arm of the sea, called the Swale, which bounds it on the south, and which is navigable for vessels of 200 tons burthen. It is about eleven miles long and eight broad. About one-fifth of the island only is arable, consisting chiefly of a deep stiff clay. The other four-fifths consists of marsh and pasture lands. The chief towns in the island are Sheerness and Queenborough, already described under these articles. See also Kent.

SHEPTON, Mallet, a market town of England in Somersetshire. It is situated about five miles east of Wells, in a low recluse valley, well watered by several branches of the river Brue. It contains above twenty streets and lanes, the most important of which are spacious and tolerably built, and meet in the form of a cross on the roads from Bristol and Bath to Ilchester, and from Frome to Wells. The smaller streets are narrow and dirty. The church, which stands on the east side of the market place, is a large and handsome edifice, in the pointed style of architecture, having a tower at the west end surmounted by a spire. The pulpit and font are each cut out of one solid stone, and seem to be of great antiquity from the rudeness of the workmanship. The monuments in the church are numerous but not remarkable. The market place contains a curious stone cross erected in 1500. It is composed of five arches, sustained by five-sided pillars, with a six-sided column in the centre. From the roof, which is perfectly flat, there arises a lofty pyramidal spire ornamented with Gothic arches, and terminating with an oblong entablature, containing a figure of our Saviour on the cross, &c. There are here also places of worship for the Methodists, Presbyterians, and Quakers. This place has been long celebrated for its manufacture of broad cloth and knit stockings, carried on both in the town and its vicinity. Nearly 200,000 yards of broad cloth were manufactured annually, and employed nearly 5000 hands. The county bridewell is within the town; and besides a well endowed free school, it has an alms-house for eight poor people. Population 5104. See the *Beauties of England and Wales.*

SHERARD, James. See Botany.

SHERARD, William. See Botany.

SHERBOURNE, a market town of England, in Dorsetshire, is agreeably situated, partly on the declivity of a hill, and partly on the fertile vale of Blackmore. The town is of a square form, the principal streets, which extend east and west, being crossed by smaller ones extending north and south. The church, which is the principal public building, is a large and magnificent one, built entirely of freestone, in the form of a cross. Though it displays various styles of architecture, yet the greater part of it is in the pointed style. The principal part of the building is nobly ornamented with tracery work, and the interior is light, spacious, and lofty. Within it are interred Ethelbald and Ethelbert, two of our Saxon kings. Among its numerous monuments, is one to a daughter of William Lord Digby, on which is inscribed the beautiful and well-known epitaph of Pope,

Go, fair example of untainted youth, &c.

The other public buildings are the market house, the free grammar school, a meeting house for dissenters, the work-house, and an alms-house. The two masters of the free school must be clergymen, and graduates of either university. The school occupies part of the site of the ancient abbey. There are also here two charity schools, three benefit societies, and a very peculiar association, called the *Green Girl's Society*, founded 1771 by Mr. Toogood. The members of this institution wear a green dress, and straw hats, and levy a small sum weekly, till they reach a certain age. At 18 they may leave the society; and those married before 25 receive L. 12 at their wedding. Those who continue unmarried till 25, receive the same sum.

Previous to the reformation, the woollen manufacture flourished here. A silk mill was established in 1740; and the silk manufactory, which is still carried on, occupies part of the buildings of the ancient monastery. The linen manufacture is likewise carried on here. Population of the town above 2000.

SHERIFF, See Law. See also our article Scotland.

SHETLAND.

This province is so little known, though, from causes which we shall explain, daily acquiring greater political importance, that we shall afford to the description of it a greater space than, under other circumstances, we are justified in doing. The account we now give is chiefly derived from Dr. Hibbert's volume on Shetland, to the examination of which country he devoted nearly two summers.

The cluster of islands and rocks which, under the name of Shetland, form the northern barrier of the British kingdom, are, with the exception of two of them only, contiguous to each other. If these be excluded from the number, the rest may perhaps be placed, (for we have no good charts of the country,) between 59° 48′ 30″, and 60° 52′ north latitude, and between 52′ and 1° 57′ of west longitude from London. The two remote islands are named Fair Isle and Foula. Fair-Isle is situated about twenty-four miles to the south of the mainland in Shetland, and Foula about twenty miles to the west.

The largest island of Shetland is named the Mainland, which stretches from north to south to the distance of sixty English miles, while its breadth from east to west varies from three to twenty-four. Yell is the next in extent, and afterwards Unst. Lesser islands are Fetlar, Whalsey, Mickle Roe, Foula, and Fair-Isle. But there are countless other islets, holms, and skerries, which it would be in vain to enumerate. Lerwick is the chief town, but the acknowledged seat of legislative authority is Scalloway.

The deficiency of good charts of Shetland is severely felt in the navigation of the northern seas. A want of light-houses was also long complained of, but this grievance has been in part remedied. On the southerly extremity of the Mainland, at Sunburgh head, a lighthouse has been recently erected, under the direction of Mr. Stevenson, civil engineer, whose projection of the Bell light-house is a monument of skill so honourable to the architecture of Scotland; and it is to be hoped that other beacons, equally required on the north and west of the coast, may render these islands no longer the terror of the northern mariner, who, fearing to be benighted near their destructive cliffs, chooses to brave the elements on the open sea, rather than make the still more perilous attempt to steer for the security which the numerous harbours of Shetland are well calculated to afford.

I. Natural phenomena and productions.

Geology and Mineralogy.—The geology and mineralogy of the Shetland islands have been very minutely detailed by Dr. Hibbert in his description of the country. The rocks are for the most part of the primary class. Granite, gneiss, and primary trap, are very abundant in the Mainland. Gneiss is a prevailing rock in Yell and Whalsey, it also occurs in Unst and other places. Mica slate and clay slate are in several places found. Primary limestone is met with in most of the islands. Serpentine rock and diallage rock prevail in Unst and Fetlar, and occur at Feideland and Hillswick. Quartz rock and primary sandstone are very abundant in the district of Walls in the Mainland, and in Foula. More rare rocks are talcose schist, and chlorite schist, which occur in the districts where serpentine prevails. The old red sandstone and secondary porphyry are the rocks of Papa Stour, and the west of Northmavine.

The highest hill in Shetland is Roeness hill, which attains an elevation of 1447 feet. The hill of Foula is next in height, being about 1300 feet.

In this singular group of islands, nature has assumed her wildest dress. We everywhere see barren and leafless mountains, rocks piled upon rocks, affording in their hollows deep lodgements for water: woodless tracts, the haunt of wild mountain sheep, the prospect being closed by the northern ocean, varied only by wild skerries. By the action of the sea upon the coast scenery is formed of the sublimest description. In the island of Papa Stour there are numerous romantic caverns produced from this cause. On the east of this island a high insulated rock is perforated through and through, and as we endeavour with a boat to trace through a frightful gloom its various sinuosities, a break of day light suddenly rushes through an irregular opening made from the summit of the crag, which serves to light up the entrance to a dark and vaulted den, through which the ripples of the swelling tide in their passage through it, are converted, by an echo, into low and distant murmurs. On the north-west of the island, Lyra Skerry, Fulgœ Skerry, and other insulated rocks and stacks, rise boldly out of the sea, richly clothed on their summits with stripes of green turf, but presenting perpendicular sides, and entrances into dark caverns that resemble the vaulted arches of some Gothic crypt. In Lyra Skerry, so named from the multitude of lyres or puffins by which it is frequented, there is a perforation throughout its whole breadth: yet so violent are the currents that force their way through it, that a passage is forbidden to the explorer, except when the ocean shows no sterner wrinkles than are to be found on the surface of some sheltered lake. On the west of Northmavine a large cavernous aperture, 90 feet wide, is the avenue to two immense perforations, named the Holes of Scraada, where, in one of them that runs 250 feet into the land, the sea flows to its utmost extremity. Each has an opening at a distance from the ocean, by which the light of the sun is partially admitted. Not far distant, Doreholm rises from the surface of the sea, hollowed out on the west by the incessant action of the waves into an immense arch 70 feet high. Again, at Burrafirth, in the island of Unst, a large cavern communicating with the water, exhibits a grand natural arch, which is the entrance to a passage that admits of the sailing of a boat to a distance of 300 feet. In the vicinity of Magnussetter Voe appears the small holm of Eagleshaw, where a perpendicular vein of greenstone, softer than the included mass of the same kind within which it is contained, has yielded to a progress of disintegration, so as to convey the idea of a deep rent, dividing the island into two unequal parts. Nearly the whole of the west coast of the island of Mickle Roe is shaped into deep winding caves, some of which are of singular beauty and grandeur. The isle of Eshaness or Northmavine, which is exposed to the uncontrolled fury of the western ocean, presents a scene of unequalled desolation. In stormy winters, huge blocks of stones are overturned, or are removed far from their native beds, and hurried up a slight acclivity to a distance almost incredible. In the winter of 1802, a mass, eight feet two inches by seven feet, and five feet one inch thick, was dislodged from its bed, and removed to a distance of from eighty to ninety feet. The bed from which a block had been carried away in the year 1818, was seventeen and a half feet by seven feet, and the depth two feet eight inches: the removed mass had been borne to a distance of thirty feet, when it was shivered into thirteen or more lesser fragments, some of which were carried still farther, from 30 to 120 feet. A block, nine feet two inches by six and a half feet, and four feet thick, was hurried up an acclivity to a distance of 150 feet. A mass of rock, the average dimensions of which may perhaps be rated at twelve or thirteen feet square, and four and a half or five feet in thickness, was first moved from its bed, about fifty years ago, to a distance of thirty feet, and has since been twice turned over. But the most sublime scene is where a mural pile of porphyry, escaping the process of disintegration that is devastating the coast, appears to have been left as a sort of rampart against the inroads of the ocean;—the Atlantic, when provoked by wintry gales, batters against it with all the force of real artillery, the waves having in their repeated assaults forced for themselves an entrance. This breach, named the Grind of the Navir, is widened every winter by the overwhelming surge, that finding a passage through it, separates large stones from its side, and forces them to a distance of no less than 180 feet. In two or three spots, the fragments which have been detached are accumulated in immense heaps like the produce of some quarry. In Lunna several large detached rocks, named the Stones of Stephouse, appear at some little distance from the sea: they are the *transported* or removed stones of geologists. The largest of them is about twenty-three feet in height, and ninety-six feet in circumference. Near Quendal bay, the phenomena of blowing sand are in a remarkable manner exhibited: here may be detected the ruins of scattered buildings which have long since yielded to the removal of the light sand that laid bare their foundations. In 1768 there were evident signs of a submarine volcanic eruption in the vicinity of Shetland, though of small extent. Vast quantities of shell fish of different kinds were thrown ashore along with conger eels and other kinds of fish; at the same time the water in the bays was so black and muddy for eight successive days, that when the fishermen were hawling haddock, or any small fish, they could not discern them until taken out of the water. It is highly unfortunate that no naturalist then existed in Shetland capable of instituting a scientific research into the circumstances connected with a phenomenon so novel to the British islands.

The minerals found in Shetland are various. At Sandlodge, copper mines were, in the year 1802, wrought by a party of Welsh miners; and in the course of two years, 470 tons of copper ore were exported to Swansea. It appears that brown hæmatite was a plentiful production of the vein, but copper pyrites constituted the object of search. Near Fitfiel Head, is a large vein of iron mica, about 12 feet broad, which traverses strata of clayslate; this has been described by Dr. Fleming, as well as a vein of copper which occurs in Fair Isle. A very thick bed of iron pyrites, nine yards broad, occurs at Garthness, which was empirically worked, at a great expense, in the hopes that it would ultimately change its character, and turn out a copper mine. In the year 1817, Dr. Hibbert discovered that the hills of Unst and Fetlar abounded with that valuable substance the chromate of iron, which is in great demand, for the purposes of dyeing, and for a pigment used in the arts; for this service rendered to the natural resources of the British islands, he received from the society of arts and commerce their gold medal. Another rare mineral which he discovered at the same time, was the hydrate of magnesia, occurring at Swinaness in Unst. Its mineralogical characters were described by Dr. Brewster. Actynolite, cyanite, amianthus, garnets, (in very fine crystals,) talc, &c. are plentifully found. The native oxide of chrome was first noticed by Dr. MacCulloch.

Seas.—The phenomena connected with the tides are well worthy attention. At Sumburgh-head, on the south of the mainland, there is what is named a *roust*, the term being of Scandinavian origin, said to signify a strong tumultuous torrent, occasioned by the meeting of rapid tides. This phenomenon may be considered in connection with the wave of tide, which is propagated from the great diurnal undulation of the Atlantic, and which, in the progress of completing its circuit round Britain, is described by naturalists, as passing to the west of Orkney, from thence to the north of the British isles, and then taking a southerly direction, so as to form a ridge that extends between Buchan and the Naze of Norway. The tides of Shetland are induced by lesser currents, generated during the progress of this wave along the westerly, northerly, and easterly parts of the country; and these set in nearly an hour sooner on the west than on the east coast of these islands. At the beginning of the flood, the tide in the roust is directed to the eastward, until it passes the promontory of Sumburgh; it then meets with a south tide, that has been flowing on the east side of the country, when a divergement takes place to the south-east, and lastly to the south. At high water, there is a short cessation of the tide, called the *still;* the ebb now begins, first setting north-west, and then north, until the commencement of the flood. In short, the various directions of tide, modified as they are by the number and form of the headlands of the coast, show that the currents are propagated at successive intervals of time; it is evident, therefore, that at the northerly and southerly extremities of the Shetland archipelago, they will be opposed to each other. Thus, a sloop has been five days becalmed between Fitfiel Head and Sumburgh, (two headlands in the southerly extremity of Shetland,) without being able to pass either point, one current carrying the vessel into the eastern, and the other into the western ocean; and although the vessel was often transported by the tide very near the shore, yet another tide always carried her off again. But although there is an opposition of currents, which extends from Sumburgh even to Fair Isle, the proper roust is that part of the stream which lies at a small distance from the promontory, the force of which is increased by its proximity to the coast, and by the shallowness of the water. Here there is always a heavy sea; but in a storm, the waves rise mountains high.—A second spot where a roust occurs, is at Scaw, the northerly extremity of Scotland.—A third is in the tumultuous channel of Blomel Sound, which separates the west of Unst from Yell. As this channel communicates with both the eastern and western seas of Shetland, tides propagated during the circuit of the great wave, at successive intervals of time, will here be naturally opposed to each other. Sir Robert Sibbald has long since remarked, that the tide in Uyea Sound, on the east of Unst, flows an hour later than that of Blomel Sound on the west, though only two miles distant; and Mr. Gifford has also stated, that when the great current in the middle of the Sound sets north, there is an eddy, deriving its course from opposite shores, that sets as fast south, and so shifts about as the great current alters.

Again, with regard to the great wave of tide itself, it is a curious circumstance, that while specimens of pumice, thrown on the shores of Shetland, indicate directions of current from Iceland, the West Indian products, known by the name of molucca beans, which float to the coast, should give tokens of extensive and opposite currents, branching from the gulf streams that are directed from the south-west. Three descriptions of the seeds that are cast on the shores of Shetland have been enumerated by Mr. Patrick Neill; the first of them belongs to the *Mimosa scandens* of Linnæus, the second to the *Dolichos urens*, and the third to the *Guilandina Bonduc*.

Other marine phenomena worthy notice, are those which are connected with the occurrence of innumerable low rocks that lie a little below the surface of the water. Inequalities of this kind, named in Shetland *Baas*, and in Feroe *Boffves*, which interrupt the currents of tide, and raise immense high waves that break, may be found at various depths, some of them having upon them as much as twenty fathoms of water. When the sea is disturbed, the breaking is repeated a few times, not exceeding seven, and before it recommences, a long interval of stillness succeeds. It is a popular opinion, that the breaking of a Baa may be induced by hot weather;—that when it takes place in calm weather, an approaching storm is indicated, and that though a Baa appear perfectly still, if a boat approach or go over the place, where it lies, a breaking, often fatal to the crew, immediately ensues. DEBES, in his history of Feroe, notices the latter circumstance, and with much ingenuity supposes, that a magnetic sympathy possessed by the hidden rock, attracts the iron of the boat, which the shallow water, in its magnetic antipathy, "not being able to endure, riseth itself." The Shetlanders, whose imaginations have conceived of strange wonders in the seas, entertain similar notions of the existence of submarine magnetic rocks.

Meteorology, &c.—We are not aware that the mean temperature of Shetland has ever yet been determined. The climate is very variable. In summer the days are of such a great length, that the morning and the evening, to use the words of a poet, "seem to melt into each other." It has been remarked by the late Mr. Mouat of Gardie, that in winter, the sun is five hours and twenty-five minutes above the horizon, but owing to refraction, the daylight is, in clear weather, prolonged to about seven hours and a half. But the most decided indication of winter is the brilliancy with which the evening is lighted up by the aurora borealis, streamers of a reddish-yellow colour darting over the heavens with a tremulous and curved motion. Whether these meteors are *heard* as well as seen, is a question still *sub judice*. There is not an inhabitant of Shetland that does not confess to the evidence of sound. Mr. Dalton of Manchester, from his experiments on the great height of the aurora borealis, as it was noticed some years ago in the north of England, maintains the negative, and that there must be some fallacy in the popular notion.

Botany.—Shetland, according to Mr. Neill, cannot boast any very remarkable plants. Nor are there any groves; the wild and remarkable scenery that this country exhibits being formed from mere rocks and water. Native willows are dwarfs; they appear only a few inches high; when they attain a greater height, it is owing to some particular shelter that they have accidentally acquired. Still, it is evident that larger trees once flourished. On the low land near Girth's voe in Delting, the encroachment of the sea, long since exposed the remains of a very ancient forest, consisting of hazle and several larger aquatic plants, the stocks of which were from half an inch to eight inches in diameter, that struck their roots into a bed of gravel, while above them was an accumulation of peat-moss about ten feet in thickness. It is also proved in digging for peat, that certain kinds of small trees, such as hazles, willows or birch, once braved with success the cutting blasts of Shetland. The causes that have led to the disappearance of these trees, is involved in mystery; it may be in part referred to the cattle that roam abroad. In the gardens of Busta and Scalloway, several trees, such as mountain ashes, planes, and elders, thrive, owing to the protection which they receive from a high wall; but no sooner do they get above it, than they are stunted. What the result could be if trees, instead of being brought from Scotland, were derived from the colder regions of Norway, no experiment has yet determined. In the parish of Delting some few small mountain ashes, (supposed to be native ones) may be found in sites where they are well sheltered and secure from the attacks of cattle.

Zoology.—The Zoology of Shetland has hitherto met with far less examination than it deserves. The shelty, the diminutive horned cattle, and the small hogs, will be noticed in our description of the agriculture of Shetland. The shores of Shetland afford numerous coverts for sea-otters, whose food, which they collect from the sea, principally consists of the conger eel. Their skins were once in great requisition as an article of commerce by the Hamburghers. The Phoca Barbata, about seven or eight feet in length, is a frequent visitant. The lesser seals are exceedingly abundant, covering in droves the ledges of the rock. The seas again abound with the mightier inhabitants of the deep. The finner is not unfrequently seen, though this may consist either of the *Balænoptera* Gibbar, the *Jubartes* or *Rorqual* of La Cepede. One of the latter kind was killed a few years ago in Unst. The *Delphinus Orca* or *Chaffer*, anciently the dread of the boatmen, the *Squalus Maximus*, the *Delphinus Deductor* or *Ca'ing* whale, with huge porpoises, add to the formidable list. The large lake of Strom, that has no communication with the sea but by an inlet, a very few feet in breadth, and which abounds with marine animals, is rendered interesting by the researches of Dr. MacCulloch, who has thereby strengthened his notion, that cod and other fish may be habituated to an element of fresh water.

The ornithology of Shetland is highly interesting. The eagle, the bonxie, or scua gull, and the *strix bubo* are among the larger of the feathered natives. The low lands, remote from the sea, are frequented by parasitic gulls that build among the heather, while the surface of the hills swarms with plovers, royston crows, sea pies or curlieus. The skerries and rocks that rise but a small height above the water, are the resort of the tern or the *Sterna hirundo*, named by the Shetlanders the tirrock. The taller cliffs, as of Eshaness, Fair-Isle, Papa Stour or Foula, abound with other kinds, as gulls, scarfs, the tomnorry, the kittywake, maws, lyres, sea parrots or guillemots. Fair-Isle was in the beginning of last century noted for hawks, affirmed to be the best in Britain. Mr. Lawrence Edmonstone has written some interesting papers on the ornithology of Shetland.

Animals of the crustaceous, shelly, and coralline species have hitherto met in Shetland with little examination, except from Dr. Fleming, who, during the time he held a living in Bressay, enriched the Zoology of Britain with several new acquisitions.

II. History and antiquities of Shetland.

Civil History and Antiquities.—The history of Shetland is much involved in that of Orkney. Near the close of the first century, when Agricola sailed round Britain, Orkney was inhabited by a people, of whose race, whether Celtic or Gothic, not the least light is to be elicited from the pages of history. Agricola saw Shetland from the shores of Orkney, and gave it the name of *Thule*, (*Dispecta est et Thule*,) an appellation that was applied to other northern countries, of which the Romans had little information. Orkney and Shetland were next the lurking places of Saxon rovers, who were routed in the year 368 by Theodosius. That the Romans actually visited the coasts of Shetland, is highly probable, from the coins of this people which have been discovered. These are of Galba, Vespasian, Trajan, and Ælius Cæsar. The remains of a very small Roman camp are to be detected in the island of Fetlar.

The Northmen, whose piracies were for several centuries formidable to Europe, were the next people who succeeded to the possession of Shetland; its numerous bays or *voes* affording secret refuge for their vessels. Indeed from this latter circumstance, they acquired the name of Vikingr, (*i. e.* bay-kings.) From this place, as well as Orkney and the north and west of Scotland, the Northmen made descents upon the rich coasts of Europe, and devastated them with fire and sword. By these pirates, Shetland was said to have been first named. "Hialtlandia vel Hiatlandia," says Torfæus, "prisco sermone semper usurpatur an a capulo gladiorum, qui *hiallt* appellatur, denominata sit incolæ viderint." Hence arose *Yealtaland*, the name that the natives gave to their country a century ago or more. Another name was Hetland, signifying the *high* or *lofty* land. Norwegian writers say that Shetland is a corruption of this word.

The remains of the forts which the Vikingr erected in Shetland are very numerous, and form some of the most remarkable remains of antiquity to be found in Europe. The burgh of Mousa, situated in the island of that name, has been described by Dr. Hibbert. "The burgh of Mousa occupies a circular site of ground, somewhat more than fifty feet in diameter, being constructed of middle-sized schistose stones of a tolerable uniform magnitude, well laid together, without the intervention of any cement. This very simple round edifice attains the elevation of forty-two feet; it swells out, or bulges from its foundation, draws smaller as it approaches the top, when it is again cast out from its lesser diameter; which singularity of construction is intended to obviate the possibility of scaling the walls. The door that leads to the open area contained within the structure, is a small narrow passage, so low that an entrance is only to be accomplished by crawling upon the hands and knees; and in creeping through it, the wall appears to be of the great thickness of fifteen feet, naturally leading to the presumption of a vacuity within. The open circular area included within this mural shell, has a diameter of about twenty-one feet. On that part of the wall within the court, which is nearly opposite to the entrance, the attention is excited by a number of small apertures resembling the holes of a pigeon-house. There are four vertical rows of them, having each an unequal proportion of apertures, varying from eight to eighteen in number. On examining the interior of the mural shell it was found to contain chambers, to which these holes imparted a feeble supply of light and air. Beneath the whole, at a little distance from the ground, an aperture led to a winding flight of some steps, of the width of three feet, which communicated with all these apartments; the shell of the burgh being composed of two concentric walls, each of about four and a half to five feet in breadth, while a space of nearly a similar dimension was the width of the enclosed apartments. These steps wound gradually to the top of the wall, communicating at regular intervals with many chambers or galleries, one above another, that went round the building; they were severally of such a height, that it was possible to walk within them upright. The roof of the lowest chamber was the floor of the second, and, after this manner, seven tiers were raised. No roof had ever protected the summit of the building, so that the burgh of Mousa was originally nothing more than a circular mural shell, open to the top. The height of the inside wall was thirty-five feet, being seven feet less than that of the outside; which difference was partly owing to the accumulation of stones and earth which had filled the inner court.

The mode was now evident in which the burgh had been intended to give security to the persons and property of the ancient Vikingr of Shetland against the sudden landing of their incensed enemies. The tiers of galleries contained within the thick walls would afford a shelter to females and children from the missile weapons of the besiegers, besides being repositories for grain and other kinds of property. Here also were kept the stores whereby a long siege might be sustained. The low narrow door within the court, which admits of no entrance but in a creeping posture, was easily secured at a short notice by large blocks of stone. It is indeed recorded of the rude forts of the Scandinavians, that they were seldom taken by an enemy, unless by surprise, or after a long blockade; that frequently terraces and artificial banks were raised on that side of the wall which was the lowest, and that the besiegers were then annoyed with arrows, stones, boiling water, or melted pitch being thrown from the fort;—which weapons they did not fail to return. The history of the burgh of Mousa confirms this observation. Its high walls bulging out from their centre, defied any attempt to scale them; for, when they were encompassed by one of the earls of Orkney, he had no hopes of inducing the fortress to surrender, but by cutting off all supplies of food, and then waiting the event of a long siege."

The burgh of Burroland is a place of defence that seems to have been originally of greater extent than that of Mousa. The inside diameter of this circular fort is about forty-eight feet, and it is formed of concentric walls, each from ten to twelve feet in width, between which are many chambers. The fort is situated on a point of rock near the sea, the land side of which was originally defended by a stone rampart.

"The fortalice of Cullswick is constructed of unhewn stones of granite, closely built, without any cement; it exhibits a double concentric wall, inclosing a space twenty-six feet and a half in diameter. The thickness of the outer wall is four feet, and of the inner wall three and a half feet, while the interval is two feet wide. Its original height is unknown. The mural construction is supposed to have been the same as that of Mousa. The burgh was surrounded by a ditch now filled up, the breadth of which was thirteen feet. An outer rampart, nineteen and a half feet broad, secured the whole.

Other burghs have a more simple structure; they are destitute of stairs within, and merely contain one tier of chambers, accessible from the inner area. Thus the burgh of Burrafiord is formed of uncemented stones, having a single wall 13 feet thick, with 11 small round apartments, each of the diameter of five feet, which were entered from within the internal area of the burgh: the roof of each were formed of stones, that, projecting over each other, drew to a point; the area included within the fort was 31 feet. The burgh was situated on a holm, or small islet, being well protected by the sea on all sides.

Near Houbie in Fetlar are the ruins of two burghs. One of them was a circular fort, formed by a double wall, with chambers between them; it was situated on a bank close to the sea, being further protected by segments of three concentric ramparts, and by one cross or flanking wall.—Frequently also the foundations of numerous houses may be traced on sites adjacent to a burgh, which appear to have been under the protection of this fortalice.—Other varieties might again be noticed, but they would occupy too much space in our pages.

Some remarkable indications of the presence of the Vikingr are the *Steinbartes* or stone axes, which were in use by all the Gothic tribes of Europe even so late as the eighth century. Fine specimens of these weapons are preserved in the museum of the Society of Scottish Antiquaries.

Another description of antiquities, of a very remote date, consists of the watch towers which cover the summits of the high hills, as of Roeness Hill, Saxavord in Unst and other places. The watch tower of Roeness hill, wantonly destroyed a few years ago by some soldiers, was of a circular shape, composed of rude uncemented stones of granite, and capable of containing within it about six people. But probably a much older construction of this kind is on the summit of a hill, in the island of Veinentry. It was about fifteen feet in diameter; within, was an irregular cavity that was entered by a strait passage, about two feet long, and one broad, being narrow near the entrance, but widening out at its opposite extremity. The height of its external cavity was ten feet; its narrowest width five, and its greatest ten feet; it appears to have been roofed with large flat pieces of granite. The cavity was probably intended for the purpose of containing within it the peat or fuel necessary for lighting a fire on the alarm of invasion. This was the province of the *ward madher*, or watch-man, a sort of sentinel, who stood on the top of a Vord Hill, and challenged all who came in sight. We read in early Orcadian Annals, of a spy being landed on Fair-Isle, who was commissioned to secretly drench the wood which had been stored up for the purpose of being kindled whenever an enemy appeared off the coast.

In the tenth century, the Scandinavian pirates of Orkney and Shetland, began to turn their arms against the mother country of Norway; but Harold Harfagre visited their haunts, and annexed the whole of these islands to Norway.

The Shetlanders were then *Udallers*, so named from the conditions under which they held their lands, the word *udal* being compounded of *œde* and *dale*, signifying a waste or uninhabited dale. Originally, any Norwegian might occupy such land as was uninhabited or waste: an Udaller, therefore, was at first nothing more than the proprietor of land previously accounted waste, which he had enclosed for his own use. But as land became more valuable, the expression gradually lost its primary signification; and when military tenures were introduced, it was merely used as a term in contradistinction to that of feudal; the word udal, in its application to land, meaning *absolute property*, that of *feudal*, stipendiary property. The udal rights were likewise protected by definite laws. The law of inheritance was in Shetland the same as in Norway;

by the latter Scottish settlers, it was thus explained, "it was a law in all times bygone, that, when any landed man departed this mortal life, his whole lands and heritage, immediately after his decease, were equally divided among his whole children, as well sons and daughters, counting always two sisters' parts for one brother's part: and being so divided, the eldest brother had no further prerogative above the rest of his brothers, except the first choice of the parts and parcels of the land divided."

It appears, however, that Harold Harfagre had placed some limitations in Orkney and Shetland to the free manner in which enclosed land was held. From the numbers of sheep which grazed on the uninclosed heaths and moors, the monarch levied a tax or scat; hence the name given to the land of *Scathold:* but the land which was actually enclosed for cultivation became free from scat, and retained for itself the true character of udal land. During the time that Shetland was under the influence of successive earls of Orkney, few events are recorded except insurrections against the yoke of Norway, intestine factions mixed with bloodshed, or descents upon the Scottish shores. Shetland being by a wide and stony channel separated from Orkney, had a distinct prefect or governor, appointed over it, who acquired the name of Foude, an office which likewise included in it the guardianship of the revenues of the country. The country, at the same time, acquired the name of a *Foudrie.* In the lake of Strom in Shetland, is shown a small holm, on which are the remains of an ancient burgh, where, according to tradition, a son of one of the Earls of Orkney fled in order to evade the wrath of his father; but, meeting with pursuers, was slain in a contest with them on the strath of Tingwell. When tidings of the event were brought to the Earl, he ordered the perpetrators of the deed to be instantly put to death, and erected a large stone where the slaughter had been committed. The stone is still remaining.—The relics of antiquity connected with the Norwegian government of Shetland are various. Courts of judicature, or tings, were held in the open air, being for the most part constructed of loose stones, which were piled together in a circular form. Of these tings, the sites of many of which are still visible, there were three kinds. The lowest was a Herad or parish ting, over which the *Foude* of the parish presided; an officer, who, in the Scottish period of the history of these islands, afterwards assumed the name of bailiff. The foude was assisted in his magistracy by a lawright man, whose particular duty it was to regulate the weights and measures, and by a number of men named Ranselmen. The ting to which these men gave their service, could only doom or give judgment in small matters, namely, in those which related to the preservation of good neighbourhood, as in questions of minor trespasses on land, poundage of cattle, &c. &c. A higher court was a circuit ting, over which the Earl of Orkney presided, or, in his absence, the *great* foude, so named in contradistinction to the subordinate or parish foudes. In his judicial capacity the great foude was the lawman of Shetland, and gave doom according to the Norwegian Book of the Law. The lawman made his circuit round the whole of the more comprehensive juridical districts of the country, named *ting sokens:* each ting soken including several minor districts, which were severally under the subordinate jurisdiction of parish foudes. He here heard appeals against the decrees of parish tings, and tried weightier offences, such as were visited with heavy fines, or confiscations, and capital punishment. A third ting was named the *lawting*, because it was a legislative assembly. This was held once a year, and here also the lawman presided. All the udallers owed to it suit and service. The law ting was held within a small holme or islet, situated in a fresh water lake, the communication with the shore being by stepping-stones. The valley in which the law ting was situated, bore the name of Thingvollr, now corrupted into *Tingwall.* Here the udallers exercised the power of reversing the decrees of inferior courts, of trying important causes, and of legislating, or making bye-laws for the good of the whole community. The highest appeal was to the king at Bergen.

Interesting remains of these tings are to be traced at the Hill of Crucifield in Unst, at the island of Fetlar, and other places. The holme of Tingwall still exhibits the circle of stones where the law ting was held. (*For a description of the tings of Orkney and Shetland, see a Memoir by Dr. Hibbert, published in the second volume of the Transactions of the Society of Scottish Antiquaries.*)

In 1379, owing to the failure of the male line of the Earls of Orkney, Henry, Earl of Sinclair, received an investiture of the Earldom from the King of Denmark and Norway, and afterwards the right of Denmark became pledged to the Scottish crown, with a stipulation that the ancient laws of the udallers should be preserved inviolate. Scottish settlers then gradually introduced themselves into Orkney and Shetland. The latter province was styled *Hialtland*, but more commonly Yealtaland; which name, by the new comers, was shortened into Yetland: hence the transition of Yetland into Zetland was an easy one, the Z in the ancient Scottish dialect, and even still in vulgar pronunciation, sounding like Y.

In 1391 there was contest between Henry Sinclair, Earl of Orkney, and his cousin, Malis Sperre, relative to a question affecting the right of the former to the Earldom. The scene of the rencontre was in Shetland: Malis and seven of his companions were killed, while other seven fled in a six-oared boat, and took refuge in Norway. Owing to this event, the government of Orkney was intrusted to other hands, and Henry Sinclair and his successor, rendered their acknowledgments to King Eric of Norway for Shetland only; but in the year 1434, William Sinclair was reinstated in the undivided possessions of the family.

In the year 1530, King James the Fifth was induced to make an hereditary grant of the estate of the crown in Orkney and Shetland to his natural brother, James Earl of Moray. When the islanders saw that a feudal superior was intended to be interposed between them and the sovereign, they were alarmed that the ancient laws of the country were about to suffer a corresponding change: headed, therefore, by Sir James Sinclair the governor of Orkney, they arose in arms to resist the arbitrary innovation. Among the Shetland insurgents were Edward Sinclair of Strom, and Sinclair of House Island. The Earl of Caithness and his kinsman Lord Sinclair were sent out against them: the udallers met their opponents on the confines of Steinhouse; and in a sanguinary conflict, the Earl of Caithness and five hundred of his followers were slain, and the rest taken prisoners. It is honourable to the memory of the king, that he became convinced of the just cause of the udallers, in consequence of which the governor of Orkney was restored to the royal favour, and a complete reconciliation took place. Edward Sinclair of Strom (according to an old deed lately extant) along with thirty companions in arms, received a respite from the king for a nominal term of nineteen years.

In the year 1565, Queen Mary made an hereditary grant of the Crown's patrimony in Orkney and Shetland, to her natural brother Robert Stewart, son of James V. by Euphemia daughter of Lord Elphinston, who was the twenty-seventh and last abbot of Holyrood.

About this time the deposition of the queen took place; and Bothwell, sailing from Dunbar, sought a refuge in Shetland, where he met with a welcome. Bringing with him a number of retainers, an ox and two sheep out of each parish were allowed for their maintenance. But indigence at length overtaking the outcast husband of Mary, he ventured into the northern seas, and sought, by piracy, to procure a subsistence. Kirkaldy of Grange, in a vessel named the Unicorn, was sent after the noble pirate, whom he met with in Bressay Sound. Bothwell took flight, and insidiously directed his course close to a hidden rock, upon which the ship of his pursuer broke. The shoal has since been named *the Unicorn Rock*.

In 1587, the lands of Brugh were given to Hugh Sinclair and his heirs; and, in a clause of the grant, there was a special provision, that they should not descend to the family according to the laws of udal succession, but according to the rule of primogeniture adopted in Scotland. The Sinclairs maintained in Shetland an establishment of no small degree of splendour. A part of the chapel which they built adjoining their mansion-house still remains. At this time the Scottish settlers, who had gradually introduced themselves into Orkney and Shetland, endeavoured to set aside the old laws of udal succession, and to introduce newer ones more favourable to primogeniture.

In 1588, the dispersion of the famous Spanish Armada in the northern seas took place. The vessel which conveyed the Duke di Medina the commander, suffered shipwreck on Fair-Isle, where, owing to want of provisions, the crew suffered all the horrors of famine. They were afterwards released from this place, and conveyed to Quendale Bay on the mainland, where the Duke received hospitable treatment in the house of a worthy Scottish gentleman, Malcolm Sinclair. Here he remained until his vessel could be equipped. Another galleon was wrecked on the west of Shetland, the crew of which, during their detention, fortified themselves in a small island named Kirkholm, and built a small chapel, which they dedicated to the holy Virgin.

Lord Robert Stewart only resided occasionally in Shetland. He erected a house, the walls of which were remarkable for their thickness, near Sumburgh Head. For thirty years he was the indefatigable persecutor of the ancient udallers of Orkney and Shetland, in his endeavours to subvert their laws, and to wrest from them their landed possessions. These oppressions it would be a long and painful task to recount. He was several times deposed from his honours and emoluments for gross tyranny; but on account of his being a favourite at court, as often re-instated. He was created Earl of Orkney, and Lord of Zetland, and died in the year 1595. His son and successor in the earldom was Patrick Stewart, who endeavoured to complete the task his father had begun, and planned the most unjustifiable schemes for wresting udal possessions out of the hands of the unfortunate proprietors, in which he but too well succeeded. About this time Lawrence Bruce, son of Bruce of Cultmalindie, having slain a gentleman in a duel, sought refuge in Shetland. He was a half-brother of Robert, earl of Orkney, and having bought up a quantity of land from the distressed udallers, completed, in 1598, the spacious mansion of Mouness, which is built in the castellated style of that period. Over the door-way is to be yet seen an undefaced inscription:

> "List ze to knaw this building quha began?
> LAWRENCE the BRUCE he was that worthy man.
> Quha arnestlie his ayris and afspring prayis,
> To help and not to hurt this work alwayis."

But the request was in vain: owing to the imprudence of Lawrence Bruce's posterity, the estate of Mouness has passed into other hands; the castle then became uninhabited, and the rank weeds of desolation were allowed to fix their roots among its walls, and to wave with every wind.

About the year 1600, in consequence of the insecure and sandy foundation of the house which the late earl had built having given way, Earl Patrick Stewart commenced the erection of Scalloway castle; and it is scarcely possible to conceive of a more flagrant exercise of oppression than that which occurred during the execution of this structure. A tax was laid upon each parish in the country, obliging the Shetlanders to find as many men as were requisite for the building, as well as provisions for the workmen. The penalty for not fulfilling this requisition was forfeiture of property. Mr. Pitcairn, the minister of the parish of Northmavine in Shetland, then came to pay his respects to the lord of the new mansion. The earl desired him to suggest a motto for this gateway. This was an occasion of which the minister availed himself to lay before the founder of the castle the sinful enormity of that oppression which had enforced its completion. The earl's wrath was kindled, and in his rage he threatened the devout pastor with imprisonment; but afterwards, Mr. Pitcairn said to him "Well, if you will have a verse, here is one from Holy Scripture,—"*That house which is built upon a rock shall stand,—but built upon the sand it will fall!*" Earl Patrick would not receive the motto in its moral sense, but applied it to the cause which first led to the building of the new castle. "My father's house was built upon the sandy shores of Sumburgh; its foundations have given way, and it will fall; but Scalloway castle is constructed upon a rock, and will stand." Accordingly, upon the lintel stone of the gate appears the following inscription:

PATRICIUS STEUARDUS, Orcadiæ et Zetlandiæ
COMES, I. V. R. S.
Cujus fundamen saxum est, Dom. illa manebit.
Labilis e contra, si sit arena perit.
A. D. 1600.

Scalloway Castle is a square formal structure composed of freestone brought from Orkney, and of the fashion of many houses of a similar date in Scotland; it is three stories high, the windows being of a very ample size; on the summit of each angle of the building is a small handsome round turret. Entering the mansion by an insignificant door-way, over which are the remains of the Latin inscription, we pass by an excellent kitchen and vaulted cellars, while a broad flight of steps leads above to a spacious hall; the other chambers however are not large. The castle is now a mere shell. The court-book of Earl Patrick Stewart during his exercise of power exhibits nothing but a horrid picture of confiscations, banishments, and capital punishments pronounced upon the inhabitants of this distracted country. At length the distresses of the udallers became so insupportable, that notwithstanding the strict guard which was placed over all ferries, so as to prevent any complaints of tyranny and oppression reaching the royal ear, a few Shetlanders made their escape, attired in the usual skin garbs of the country, and in this dress found their way to the court of James, and submitted to him, with true native eloquence, their oppressed condition. These complaints met with attention; and soon afterwards a representation from the whole of the inhabitants of Orkney and Shetland was forwarded. The Earl of Orkney was arraigned on the charge of usurping in his government the king's prerogative, and had justice administered to him too much after the manner in which he himself had dispensed it in the courts of his own Earldom. After a very unfair trial he was beheaded at Edinburgh.

Orkney and Shetland were next annexed to the crown, only to be granted to greedy farmers or tacksmen, under whom the distressed Islanders experienced no alleviation of their calamities. Afterwards the Earl of Morton, on account of money, advanced to the unfortunate Charles during his troubles, acquired possession upon mortgage of the crown estates of these islands, and usurped a direct superiority over the udal lands. But the process of feudalization was completed in the reign of Charles the II., by Douglas of Spyne, factor of the crown rents, who obliged all the udallers to take out charters from the crown, by the granting of which he raised in Shetland alone, a sum of not less than £15,000 Scots. About this time, Denmark failed for the last time in obtaining an acknowledgment from the government of Britain, that Orkney and Shetland had been merely surrendered by her on a redeemable pledge. In 1669, Orkney and Shetland were by an unjustifiable act of parliament, cancelling at once the claims of the Morton family, re-annexed to the crown, and they were again let out to tacksmen; but in the year 1707, the Morton family had sufficient interest to get reinstated. In the year 1742, the Earl of Morton, on the plea that the emoluments arising from Orkney and Shetland were not sufficient to pay the interest of the sum for which they had been originally mortgaged by the crown, obtained a discharge of the reversion; an act was therefore passed, making the whole of the estates in which he was in possession, heritable or irredeemable. Nine years afterwards, this nobleman was deprived of the jurisdiction of these islands, for which he received a sum of money in compensation, and soon afterwards he was involved in extensive suits at law with the heritors, relative to the fraudulent increase of weights and measures that had gradually taken place by the ancient oppressors of these islands: he gained his suit, but these litigations became so oppressive to him that in the year 1776 he sold all his interests in Orkney and Shetland to Sir Laurence Dundas. The new possessor afterwards conceived that his powers of superiority were too limited, and, in order to extend them involved himself in an extensive suit at law, in which he completely failed.

Such is a very faint political history of these islands. It may be added, that in 1669, when nearly all the lands were feudalized and annexed to the crown, the province then became in every respect subject to British laws. It was rendered liable to a land-tax, which was in vain disputed, on the plea that the scat already paid was a proper equivalent, and that no other could be in justice demanded. Orkney has always paid two-thirds of the cess, the remaining one-third having been rendered by Shetland; but the latter country having no valued rent, by which the right of individuals to vote can be ascertained, is denied any share in the election of a member of Parliament. Lord Dundas is the Lord Lieutenant of Orkney and Shetland: and with regard to the internal legislation of the latter country, it may be briefly remarked, that the offices of Justice of Peace have been lately revived, that the Sheriff-substitute holds a regular court, and that there are separate admiralty and commissary jurisdictions.

A century and a half ago, the town of Lerwick rose into existence. In the dutch war of 1665 a citadel had been built near Lerwick, to defend Bressay sound from the Dutch, and it was well garrisoned; but in the commencement of the 18th century, a Dutch frigate burnt the fort and several houses in the town. In 1781, it was completely repaired, and named Fort Charlotte. Since the last peace, it has become the manse of the very respectable minister of the parish.

Ecclesiastical History and Antiquities.—It is almost needless to remark, that the ancient religion of the Scandinavian colony of Shetland embraced the mythology of the Edda. Some of the antiquities indicative of the existence of this religion are the numerous cairns raised over the graves of the distinguished, which mode of sepulture prevailed throughout the whole of northern Europe. It was one of the commands of Odin, that over the remains of men of rank huge heaps of earth should be raised; but that over those who had performed extraordinary achievements, high stones should be erected, inscribed with Runic characters, which ever commanded in Scandinavia a superstitious awe. A stone of this description, bearing upon it mysterious signs, was taken from its site, and infixed in the wall of the parish kirk of Sandness. It was also a custom of Shetland, (certainly of Pagan Origin,) when any one met a funeral, to lift up three clods, and to throw them one by one after the corpse. In the isle of Uyea, some beautiful urns, wrought from a soft steatitic stone, were found in a tumulus.

Orkney and Shetland were very late in embracing the tenets of Christianity. On the south of the mainland of Shetland, the foundations appear of an old chapel dedicated to St. Ninian, commonly named Ronan. St. Ninian was a Cambrian, and zealously preached Christianity in the fifth century to the Britons of the province of Valencia or shire of Galloway. Mr. Chalmers conceives, that the chapel might have been founded by some pious Columbians of the sixth century in their visit to Shetland; but this is very doubtful. In a very early period, certain Irish papæ, or priests, sought places of refuge, during some commotion of their country, in Shetland, where three islands yet bear the name of Papa, the largest of them being called Papa Stour, or the Great Papa. But whether these priests brought over many Shetlanders within the pale of Christendom, is very doubtful. In a later period, Sigismund Bretteson, a hero whom the northern Scalds, in marvellous stories of his prowess, have celebrated in their songs, was commissioned by Olaus, king of Norway, to baptise the heathens of Shetland. But the great Christian saint of Orkney and Shetland was Magnus, once partaker, in the 13th century, with Hacon, his cousin, in the earldom of Orkney. He was a meek ruler, worthy a throne in the period of the millenium, since he refused to fight against men from whom he had received no injury. Hacon was his deadly foe; Magnus, attended with unarmed men of peace, went to meet him, by appointment, in an island of Orkney, hoping for conciliation. Hacon repaired thither, with warriors well accoutred, and instantly doomed his cousin to death. The martyr bent forward his head, and an executioner cut it off at a single blow. After his death, he was sainted by the pope; a grand cathedral was dedicated to him in Kirkwall, and numbers repaired to his tomb, where, with the assistance of proper oblations and ceremonies, they were cured of their diseases.

When a bishop of Orkney was appointed, Shetland would of course be included in the diocese. Tingwall, Whiteness, and Weisdale, formed an archdeaconry. Their union is indeed still perpetuated, by their being formed into one parish.

All the ecclesiastical buildings of Shetland appear to have been devoid of the least show and ornament, the ingenuity of the architect extending no farther than in constructing a vaulted roof, and steeples like the round ecclesiastical towers of Ireland. The pointed arch, the pinnacled buttress, or the rich stone canopy, never dignified the chapels of Hialtland. The number of them was remarkably great. The parish of Yell boasted twenty chapels, where only two or three are used at the present day. Many of these buildings may be attributed to wealthy udallers, who had a private oratory contiguous to their dwellings; others were erected by foreign seamen, in fulfilment of their vows to some tutelar saint, who had been miraculously preserved on these dreaded shores from shipwreck or from death. They were variously dedicated, to our Lady, to St. Olla, to St. Magnus, to St. Lawrence, to St. John, to St. Paul, or to St. Sineva. Near Papa Stour an insulated rock, named *Frau-a-Stack*, or the Lady's Stack, inaccessible to all but the best of scalers, is crowned on the summit by the remains of a small building, that was originally built by a Norwegian lady, to preserve herself from the solicitations of suitors, when she had entered into a vow of pure celibacy. The ascent to the house was considered almost insurmountable, except by the help of ropes. But a dauntless lover, an udaller from Islesburgh, contrived in the dark secrecy of evening, to scale the cliff, and, after the first surprise was overcome, successfully ingratiated himself in the fair devotee's affection. When the consequence of the lady's *faux pas* could no longer be concealed, Frau-a-Stack became the scoff of the island, and was deserted by its fair and frail tenant. The house was afterwards unroofed and reduced to ruin, in contempt of the vow of chastity that had been broken.

Runic inscriptions over the graves of distinguished Norwegian colonists were common; one only now remains, namely, at Crosskirk in Northmavine.

Orkney and Shetland were late in receiving the reformed religion; and when at length it was introduced by such an unworthy professor of it as Lord Robert Stewart, the *ci-devant* abbot of Holyrood, no wonder that it should be necessary, at a very late period, to issue out acts in Kirkwall, forbidding, under severe penalties, all idolatry, such as walks and pilgrimages. In the commencement of the last century, many Popish festivals were still preserved, particularly those of Halloween, of St. John's Mass, or of Whitsuntide. The people had their fasts, in which they eat fish, or, in conformity with an ancient church decree, indulged themselves with the flesh of seals, which was admitted as a lawful substitute, whenever it could be proved that these animals, in having been pursued, had betaken themselves for safety to sea in preference to dry land. Many old chapels, that had been dedicated to particular favourite saints, were resorted to so late as the beginning of the last century. The devotee would cast among the ruins of the church, as a religious offering, a small image of silver, representing any particular part of his body that might be afflicted with illness; a recovery was then fully anticipated. Even the shell-snails that infested the walls were supposed to be possessed of particular healing powers;—they were dried, pulverised, and administered for the cure of jaundice. It was also customary, long after the abolition of Popery, to walk at Candlemas to the chapel, in the dead of night, with lighted candles. Our Lady's kirk at Weisdale was resorted to in completion of promises made during perilous navigation, or during sickness. "It was much frequented," says Brand, "by women, who, when they desired to marry, went to this church, making their vows and saying their prayers there, so assuring themselves that God would cause men to come in suit of them." The mariner also placed his confidence in the offerings which he might make within the pale of the church, trusting that they would secure for him a happy voyage. Within these walls the supplicant would light candles, and even when the shrine had been destroyed, would drop money among the ruins, or would parade around the kirk on his bare knees. Nor has the custom of making oblations at Our Lady's kirk of Weisdale ever yet ceased. In the pulpit of the church a great quantity of all the different currencies of Shetland has been found, from the guilder down to the stiver; and although the building is now almost razed to the ground, the anxious fisherman still drops a pecuniary offering among its loose fragments.

In 1697, the Presbyterian form of church government was introduced into Orkney and Shetland. All lands belonging to the church then returned to the crown; but since they were not annexed to it, they were liable to be disposed of by the sovereign at pleasure. Three years afterwards, in consequence of a commission being despatched to these islands by the general assembly in Scotland, nearly the whole of the ministers conformed to Presbyterianism. The bishops' rents in Orkney were retained by the crown, but the stipends to ministers were paid out of the church funds, though in a less proportion.

The parishes into which Shetland is divided are Unst; Fetlar and North Yell; South and Mid Yell; Northmavine; Delting; Lunnasting, Westing, Skerries, and Whelsay; Aithsting, and Sandsting; Walls, Sandness, Papa and Foula; Tingwall, Whiteness, and Weisdale; Lerwick, and Gulberwick; Bressay, Burra, and Quarff; Sandwick and Dunrossness.

Parish Schools.—A century ago there was not even a school for the wealthier classes, "whereby," says Brand, "many promising and pregnant ingenys were lost;" but shortly afterwards the poor were taught by a master sent over by the Society for the Propagation of Christian Knowledge. In the year 1724, the landholders of the country met and established a school in each parish, obliging parents, under a heavy penalty, to send their children thither. Afterwards, for a long period, the education of the poor was again neglected. At the present day many schools are established in different parts of the country, although some of them appear to be ill attended.

III. The state of land and landed tenures in Shetland.

State of Land.—A more complex inquiry than this cannot possibly be imagined, and without a sacrifice of greater space in the present article than we are justified in making, we must despair of rendering the subject intelligible to our readers. In making, therefore, a general reference to Dr. Hibbert's volume for detailed information concerning the Shetland tenures, a very slight sketch must at present suffice.

In a very early and rude state of society in Scandinavia and her colonies, a *mark of land* was a measure of no definite extent, but such a portion as was considered equal to a mark of *wadmel*, (or coarse cloth); which mark of wadmel consisted of 48 ells. A newer standard of comparison which succeeded to the wadmel was a certain *mark weight* of some inferior metal, which was divided into eight ounces, each ounce being equal to six ells of wadmel.

From each mark of land in Shetland, equal in value to 48 ells of wadmel, or a mark weight of some inferior metal, Harold Harfagre levied a *scat* or tax. The scat was originally paid in a certain quantity of wadmel, but afterwards in some rude description of coin, which bore the name of pennings or pennies.

But the scat which Harold Harfagre exacted was limited to pasture or grazing land, whence the name applied to such land of *scathold*: but in order to encourage husbandry, the land which for cultivation had been separated from the scathold, and enclosed by a fence, became exempt from the scat or tax, and thus was strictly *udal*. At this early period, therefore, the quantity of scathold contained within a mark, for which a scat was due, became expressed by the number of pennies which the King of Norway actually received: thus the largest extent of scathold incidental to a mark of land was liable to an impost not exceeding 12 pennies or three ells of wadmel; while the least extent of scathold owed a tribute of not less than four pennies, equivalent to one ell of wadmel. Hence the number of pennies at which a mark of land was rated indicated the proportion of scathold or common land to which the proprietor was entitled. A considerable number of these assessments must have occurred in succession during early times, in proportion as land became enclosed for cultivation, and was by this means rendered scat-free; but as the distinction has for nearly two centuries ceased to be acknowledged, the last appreciation serves the purpose of the present landed proprietor, who estimates from the amount of the pennies by which each mark of land is still designated, his proportion of scathold or common.

This assessment has again served another purpose. When the King of Norway, who originally possessed much land in Shetland, or when the Earl of Orkney, or any other proprietor, chose to let out land upon a tenure, the rent was regulated by the number of pennies at which each mark of land was valued. One general rental of Shetland was, therefore, acknowledged. The rents originally paid were in wadmel, but afterwards butter was accepted. The weight of butter was estimated by marks, each mark containing eight ounces, while 24 marks formed a *lispound* of 12lb. weight. In a still later period, rent was less frequently paid in kind; and for the wadmel, Scots money was often substituted. After this commutation had taken place, the ancient rental of Shetland stood as follows:

Description of Land, per each Mark.		Rent due in Butter.		Computation in Money.	
12	Penny Land,	12	Marks in Butter,	16s.	Scots.
10	do. -	14 2-3	do. -	14s. 8d.	do.
9	do. -	12	do. -	12s.	do.
8	do. -	10 2-3	do. -	10s. 8d.	do.
7	do. -	9½	do. -	9s. 4d.	do.
6	do. -	8	do. -	8s.	do.
4	do. -	6	do. -	6s.	do.

But although the *nominal* rents have not been raised since the islands were annexed to the crown of Scotland, yet collusive means have effected the purpose quite as well. A lispound, the measure in which butter or oil was paid, was originally of 12lb. weight. The Stuarts, Earls of Orkney, raised it to 18lb.; the oppressive exacters of the crown rents, and needy farmers, made it 24lb. and it has since been gradually increased to 32lb. "As a consequence of this increase, says the author of the grievances of Orkney and Shetland, "numberless little heritages, and some fair estates also, are swallowed up, the crown rents having so increased with the weights, that, when the years are not very plentiful the whole fruits of the ground are not sufficient to satisfy them."

The history of the feudalization of udal lands has been given. Some very ancient patrimonies, which have never been held by a charter from the crown, are still in a limited degree udal; and those which, in a later period, were feudalized by the Earl of Morton, are enjoyed on tenures that are comparatively light. With regard to the crown lands, in the earliest tenures that were granted, the asperities of feudality were so softened down, as to be scarcely perceptible. The lands that devolved to the crown, by the virtue of the treaty of James III. in the fifteenth century, with Earl Sinclair, were named property-lands; and the king, in letting them out in triennial leases, subjected them to an annual rent, named *land-maills*, estimated according to the general rental of the country, and to a fine or composition, named *grassum*. But if a tenant wished to convert his lease into an heritable feu, the triennial compensation of grassum was dispensed with, and he merely paid the annual tribute of land-maills. When also lands were ley and not laboured, the land-maills were humanely remitted. The earliest feuars of the crown estates were named The Kindly Tenants of the King. A change, however, too soon occurred. When the superiority of the country was granted to mesne-lords, and when the revenues of the king were let out to farmers, crown-lands paid rent whether they were ley or laboured; and, in the course of time, the terms on which the rentallers of the crown were allowed to possess their lands, became very rigorous.

The rents and duties of Shetland may now be stated. All landholders still pay the scat that was rendered to the king of Norway. Lands are let subject to the ancient rental of Shetland, the materials which are still paid in kind, being estimated by the lispound of 32lb. The grassum for the king's land is now converted into an annual demand of eight shillings Scots for each mark of land. All landholders pay a duty named *wattle*, in commemoration of the prayers of a good sainted lady, which the Shetlanders, in Popish times, purchased as an intercession for their manifold sins; they also pay the ox and sheep money that was granted as a compliment to the Earl of Bothwell, when he obtained a refuge in Shetland. The average of scot, wattle, and ox money, for each mark of land, is said to be about 8d. sterling; some marks being charged so high as 1s. 4d. An old claim of trilling amount, named hawk-money, originally paid to the king in support of his hawks, is waved. The landholders pay one half of the cess or land-tax, and rogue money, a premium for killing eagles, ravens, and hooded crows; bounty to seamen and other casualties, with a proportion of schoolmaster's salary, which may altogether amount to about 6d. sterling per mark of land. The duties to the superiors, which were originally exigible in the *ipsa corpora*, are regulated by the rise or fall of butter and oil, according to the prices of the market.

Tenures.—We may now describe the manner in which lands are let in Shetland. While a proprietor has been in the habit of setting his land, according to the ancient rental of the country, he has appended the king's ancient requisition of grassum, to the amount of his land-maills, and has taken for his precedent all the other exactions incidental to the crown estates. The payment of a hen for every mark of land has been also introduced. This is the *Cane-fowl* of the south of Scotland. The landed proprietor has likewise been accustomed to exact, in addition to cane-fowls, the labour of each tenant for three or six days in the year, for the purpose of casting peats, or other labours of husbandry. This practice has been very properly condemned by Dr. Edmonstone, as one that "keeps alive the recollection of feudal oppression, and stifles the feelings of generous freedom."

But lands are most frequently let with fishing obligations attached to them. These we shall now describe.

The remarkable fishing tenures of Shetland had their origin in its former impoverished state. In the middle of the last century, owing to certain customhouse regulations which affected the foreigners who fished on the shores of Britain, there was a cessation of the periodical visits which the Hamburghers made in this country for the purpose of trading in cod and ling. There was also a decline of the Dutch herring-fishery, which gave great support to Shetland, and the weights and measures were more than double their ancient standard. The landlords, therefore, saw nothing but ruin threatening them, unless they availed themselves of the encouragement given by successive acts of parliament, towards the promotion of the British fisheries. Accordingly, they were compelled, in their own defence, to be the proper successors of the foreign merchants, who had, for the uninterrupted period of two centuries, been the chief supporters of the Shetland fishermen. But at the same time, the peasantry, from the causes stated, were in such an impoverished state, that their landlords were obliged to furnish them on trust with boats and lines necessary for carrying on the fisheries of the country. This system has been perpetuated to the present day. The landlord lets his land for one year only, in consideration of a certain rate that is regulated by the ancient rental of Shetland; he undertakes, at the same time, to advance a tenant the articles necessary for the ling-fishery, such as boats and lines, requiring from him the same profit that a buyer would expect from a seller; but in lieu of these advances, the tenant must enter into an obligation to deliver to his landlord all the fish which he takes at a stipulated price. A system such as this cannot but be objectionable; the excuse for it has been the debased political state of the country. That it opens a wide field for oppression, against the temptation of which no country, where human passions prevail, is proof, it would be absurd to deny. An unfavourable state of the weather occurring throughout the short summer season in which the fishermen repair to the fishery,—a loss of lines or boats,—any of these incidents, may oblige the tenant to become a debtor to his landlord, and, actuated by a threat of distraint or ejectment, he may assent to any slavish conditions which a task-master may choose to dictate. These are certainly very possible results that must arise from such a system.

The late Mr. Cheyne, however, of Tanwick, who was both a considerable landholder himself and a tacksman, made his dependents forget the power that the tenures of the country threw into his hands, by attending to their wants, and by encouraging their exertions in so many different ways, that, before he died, he had the satisfaction of seeing the tenants under his influence pre-eminent in the country as an industrious, enterprising, and contented race of people. His example has been imitated with success by other gentlemen in Northmavine. But this circumstance argues little in favour of the tenures of Shetland. A people may flourish under a good king, though the system of the government be arbitrary; but a system is not to be defended on this account, for a successor may rule with a rod of iron. It is, however, creditable to the present race of Shetland landlords, that they are fully sensible of the advantages to be derived from letting land at a definite price, independent of the obligation of fishing, and of paying tenants a regular price for their fish, that may correspond with the fluctuations of the market. Yet, after all, the introduction of any new description of tenures must be necessarily a slow process; the objection against it chiefly arising on the part of the tenants themselves, who, being familiarized all their lifetime to a system which they are conscious is a bad one, are, notwithstanding, unwilling to exchange it for one of which they have had no experience. It was long ago remarked by a writer, strenuous for the support of the present state of Shetland tenures, that the fishermen were so poor, that they durst not fish for themselves, fearing, that if they were deprived of the support of their landlords, they should perish for want. This assertion affords the best argument that can be produced for the necessity of a change of system. A sense of dependency in the human mind is too often the forerunner of an inactive and unenterprising state of indigence.

Hr. Hunter of Lunna, was one of the first who attempted to introduce into Shetland a freer description of tenures. But the obstacles he met with originated from an unexpected source,—from the tenants themselves, who, being by no means prepared for so sudden a change of condition, much abused the liberality they experienced. This event shows, that a domestic reform, like a political one, should be a gradual process. Mr. Gifford of Busta has also very recently followed the example. We shall be most happy to hear that the experiment will equal the hopes of this liberal-minded proprietor.

But many tenures, free from the obligations of fishing, have of late years been granted on advantageous leases, which have no precedent in the older rentals of the country. This is one of the happy consequences of the Agricultural Society, lately instituted in Shetland.

Teinds.—The teinds of Shetland are partly of corn; these are paid by some lands in every tenth sheaf, after being cut down; in other lands, the teinds are compounded for in butter and oil, and in a few lands only in money. For every thirty sheafs, three marks of wool and one lamb are exacted. For each cow, three marks of butter on an average, and for each calf, one shilling Scots. Each six-oared boat pays of teind, fifteen ling, and each four-oared boat, ten ling. In the last place, the minister claims a right to three days work from each family in the parish, for the purpose of casting, raising and bringing home his peats.

There are no poor rates; the poor are quartered upon the parishes in rotation, living in each family for periods, varying from one week to a month.

Wrecks.—In the case of wrecks on the coast, there is an admiralty court, which is empowered to judge of all circumstances relative to them, consisting of a judge, a clerk, and a procurator-fiscal. When a wreck happens, and none of the mariners are saved, it is the duty of the procurator-fiscal to state the circumstances to the judge, who appoints a person to take charge of what part of the property may remain, to sell it, and to advertise publicly that the proceeds are lodged in court, until an owner appears; and if, after the lapse of a year and a day, no claim be made, the property devolves to the Admiral. In the old law of the country, it was ordered that a third of the ship and cargo which might go ashore should accrue to the proprietors of the ground, a third to the salvers, and a third to the owner. But, throughout Britain, the provisions regarding wrecks are undergoing many wholesome regulations.

IV. State of agriculture in Shetland.

The fishing tenures of Shetland having been at length explained, a ready inference suggests itself, that they afford no possible stimulus whatever to the cause of agriculture. Indeed the natives, as husbandmen, differ little from that humble state of advancement, which has been described in a Teutonic poem of the eighth century.

> "Suis rebus contenti
> Domos edificarunt et liberos genuerunt,—
> Sæpibus segetes cingebant,
> "Agros oblimabant,
> Sues nutriebant,
> Capras custodiebant,
> Et cespites effodiebant."
> *Translation to the Song of King Eric.*

Weights and Measures.—Under this head may be included a description of the Bysmer, still greatly in use, by which was estimated Lispounds. It is of the greatest antiquity in Norway, being described by Olaus Magnus. The late Mr. M'Kenzie in his "Grievances of Orkney," has after the following manner described the Shetland Bysmer: it is a lever, which at one end is about three inches in diameter, and at the opposite end, to which it tapers, is only one inch. From the middle to the smaller extremity, it is marked with small iron pins, at unequal distances from one mark to twenty-four, or a lispund. The commodity to be weighed is hung by a hook attached to the small end of the Bysmer. The lever is then horizontally suspended by a cord going round it; the weigher shifting the cord this and that way, till the commodity equiponderates with the gross end of the Bysmer. Thus the pin nearest the cord, at the time of equilibrium, shows the weight in marks.

Public Roads.—Here is a blank.—There is no road in Shetland deserving the name of one. The only *attempt* which has been made is to no greater a distance than five or six miles to the west of Lerwick. In some parts of the country, the fine voes that penetrate far into the land, render roads almost unnecessary. But there can be no question that Shetland suffers materially by the absence of good communications between Lerwick and the westerly and north-westerly districts. Again, the want of roads is much felt from another cause. In no part of Great Britain is boat-travelling more extravagant than in Shetland. There are no regular ferries; and although the magistrates of the country have attempted to fix a rate of fares, and to express their determination, in case of any disputes coming before them, to make it their standard of reference, the regulation is altogether a dead letter. There are few gentlemen who, in the trips that they make, are not rowed by their own tenants; and they take this opportunity of ingratiating themselves in the favour of their dependents, by paying them above their due; it is, therefore, unfortunate that the sum thus given is the least that is demanded from the stranger.

Construction of Dwellings.—The oldest Shetland dwellings are built of rude stones, with a cement of clay, or they are still more coarsely formed of stones and clods. After the wooden rafters have been laid, they are often roofed with what are provincially called *flaas*, which are compact vegetable layers, consisting of the short fibres of mossy or heathy roots, closely interwoven with each other. The removal of a layer of this description from the surface of dry moss land, is never accomplished by cutting, but by tearing away. When layers composed of flaas are doubled, they are considered to be impervious to rain, and in this state are placed upon the rafters of the houses. But, instead of flaas, the Shetlanders often substitute what they call *pones*, or swards of earth cut very thin, upon the surface of which grows a short grass. A roof, formed of thin turf, has long been considered the peculiar characteristic of the Scandinavian cottage. Occasionally, however, the Scotch method of thatching is introduced, in which case, the straw is laid over the pones or flaas, and afterwards secured with *simmonds*, or straw-bands.

Towns or Rooms.—It has been remarked that the scat which Harold Harfagre exacted from the ancient inhabitants of Shetland was under certain limits; it was demanded from all pasture or grazing land, whence the name it took of Scathold; but in order to encourage husbandry, the land which for cultivation had been separated from the scathold, and inclosed by a fence, became exempt from the scat or tax. This exempt land was named by the ancient udaller a *town;* and it was not necessary that a single house should indicate its site. But when settlers from Scotland appeared, a town was named by them a *room;* the expression indicating a limited space inclosed from the commons for culture. Most of the *towns* or *rooms*, which had originally belonged to the small udallers of the country, fell, in the course of time, into the hands of some rich settler from Scotland, who attempted to connect the various small inclosures that had been made by a single dike. At this day, therefore, nothing can well surpass the irregularity of such circumscriptions, which often wind in every direction in the most zigzag manner. One dike may include thirty or forty towns; and every farmer is obliged to repair a certain extent of his fence, proportional to the land which he occupies.

Fences.—The materials of which the fences are composed, generally consist of *fails*, which differ from *pones*, used for roofing houses, in the following respect: Fails are the thickest portions of turf that are cut, being used for the construction of walls and dikes: Pones have always a covering of grass; they are thinner than fails, and they are never used for the construction of dikes, but for the sole purpose of roofing; but so imperfect are these inclosures, which consist of turf or stone, that by the incursions of sheep, horses, and swine, they are thrown down every year.

Town Mails.—There is generally a piece of green pasturage, never dug up, that is attached to each house, which, in the ancient language of the country, was named a *setter* or *seater;* the Shetlander now names it his *town mails*. On this spot horses are always tethered, when wanted for immediate use, or upon the close of a summer's day, the small horned cattle of the country are in like manner secured, previous to their being lodged for the night within the byre. These last named animals we shall next consider.

Horned Cattle.—The black cattle of Shetland are of a very diminutive breed; a cow is said to weigh from two to three hundred weight upon an average; an ox from three to four, but not exceeding five hundred weight. These animals have long small horns, and are of a brindled white, brown, or black colour, rarely displaying an uniform hue.

Cows are kept in the house every evening during the year. In the summer they are tethered during the day time in some adjoining pasture. Upon the conclusion of the ling fishery, which is generally in August, the Shetlander repairs to his scathold, and cuts down a large quantity of grass and short heath, which he spreads abroad upon the hills to dry; it is afterwards stored within the inclosure of his *room* or *town*, being piled into stacks like hay. When intended for use, the heath is strewed along the floor of the byre, for the purpose of being well mingled with the dung that accumulates from the cows. The wet stratum is then covered over with a layer of *duff mould*, or dry decomposed moss, which substance, in like manner, remains until it is well moistened with the dung that falls, when the whole is again covered with a layer of heath; and after this manner, successive strata of heather and mould, mixed with the ordure of the animal, are allowed to accumulate to a considerable height, until the pile attains such an elevation, that its removal is necessary, in order that the cattle may find sufficient head-room beneath the roof of the byre; but how far the effluvia of putrid matters may conduce to the health of the animals that inhale the tainted atmosphere of such confined places, is a question of unnecessary discussion. When the compost is removed, it is well blended together with a spade, and is then applied to the land destined for cultivation.

The food of the cows is in general so little, that during very severe winters, numbers have been known to perish for want. When Dr. Kemp travelled through the country a few years ago, so great was the dearth of food, that he witnessed a kind of mash served up for a cow, consisting of a pail filled with boiled fish-bones, which had been broken down. Such an unnatural mess, however, though by no means uncommon in Iceland, is much less frequently seen in Shetland.

Operations of the churn.—The quantity of milk given in the day by the Shetland cow is very inconsiderable, not amounting, in the middle of summer, to more than from three to five English quarts in the day. The operation of churning takes place every second or third day. A little time before the butter is about to part from the serum, the dairy-maid throws red-hot stones into the churn, by which the separation is hastened, and rendered more complete. The attention she pays to the purity of the butter depends upon its destination,—whether it is intended for consumption within the house, or must be rendered in payment for feudal duties, or for teinds; thus the proverbial quality of teind-butter, which is fit for little else than for greasing cart-wheels, is proverbial.

Into the *bledoc* or buttermilk that remains in the churn, boiling water is poured; the caseous part, or curds, then fall to the bottom of the churn and are used for food, often instead of bread. The mixture of serum and water that is left, forms a common drink, named *bland*, which, when allowed to rest, undergoes a slight degree of fermentation, and acquires, in the course of a few months, a remarkable degree of transparency, and along with it a very acid yet agreeable taste. A similar beverage is familiar at the present day to the Icelanders, among whom it is known by the same appellation that it bears in Shetland. Another product of the dairy is obtained by adding to a quantity of sour cream some sweet milk: the mixture then undergoes a fermentation, after which the whey or serous part is poured off, and more new milk is added. The process is thus repeated several times, until the firmer part resembles a custard of a sub-acid and highly pleasant taste.

Poultry and Swine.—A very great abundance of poultry is kept on almost every farm, these being very frequently inmates of the house. The most common tenants, however, of the inclosures are the small swine peculiar to the country, which are of a dunnish-white, brown, or black colour, with a nose remarkably strong, sharp-pointed ears, and back greatly arched, from which long, stiff bristles stand erect. The hog is said to weigh from 60 to 100lb. Being often very lean, his flesh is as food proportionally coarse: but when fattened the meat is sufficiently sweet and delicate, and when cured forms excellent hams.

Horses.—The little barrel-bellied, broad backed *equuleus*, of a brown or black colour, which Buchanan has described as "*asino haud major*," is well known under the name of *Shelty*. He is left to feed on the hills during the whole year: and in the most inclement weather of winter, is never admitted within the warm walls of a stable, being frequently compelled to subsist on the drift ware that is left by the ebb. In the spring these animals are often in such a half-starved state, owing to their scanty supply of winter food, that the growth of the summer herbage becomes necessary before they can so far recover their strength as to bear a rider over the moors of the country.

The shelties are seldom more than from nine to eleven hands high. They are generally used for carrying peat from the moors or manure to the fields. For this purpose a saddle is contrived, named a *klibbar*, which differs in construction from the klibbar of the Feroe islands. The Shetland klibbar consists of two flat pieces of wood that meet on the ridge of the shelty's back, being rounded off on their summit, and connected together by means of two long attached pieces of wood, which transversely fit into each other and project upwards; the boards are then secured below by girths that pass under the animal's breast and tail, while from the two cross pieces of wood that rise from the top of the saddle, are suspended a couple of *cassies*, or baskets, made of straw. These cassies are filled with the materials intended for transportation. But when hay or any light bulky substance is to be carried, *maisays* are used, which are made of ropes prepared from *floss* or rushes, these being reticulated in meshes of some inches in width. A net of this kind is passed round the horse, so as to secure the hay or other light substance that rests upon the boards of the klibbar. This ancient saddle is also found of use when the shelty is required by the female rider to bear her to the parish kirk: she then throws over his back a native coarse manufacture of the country, woven into the shape of a saddle-cloth, and when, upon this covering the klibbar is fixed, its projecting pieces of wood, which the female holds by, form it into a kind of side-saddle.

When a journey on horseback is meditated, the Shetlander goes to the scathold, ensnares the unshod shelty, occasionally equips him with a modern saddle and bridle, and hangs on his neck a hair cord several yards in length, well bundled up, from the extremity of which dangles a wooden short-pointed stake. The traveller then mounts his tiny courser, his feet being often lifted up to escape the boulders strewed in his way, and when arrived at his destination, he carefully unravels the tether attached to the neck of the animal, seeks for a verdant piece of soil, and fixes the stake into the ground. The steed is then considered as comfortably disposed of, until his master shall return.

Cutting of Peat.—It was in an early period of the historical annals of this country that the want of wood was experienced. The first Norwegian colonists were acquainted with no other kind of fuel than that which they had collected from the forests of their own native mountains, and when Einar, Earl of Orkney, pointed out to them that a fuel was to be obtained from dried peat, he was almost deified for the discovery, having ever afterwards the honorary title prefixed to his name of Torf.

It is in the time of *Voir* or spring that the Shetlander generally repairs to his scathold for the purpose of cutting his peat. Thus, there is an ancient law in the country, "that none cut floss before Lammas-day in their own scathold, without due advertising of their neighbours belonging to the same scathold, under the pain of 40s. Scots *totius quoties*." When the natives are assembled to cast their peat, their first object is to pair off the vegetating moss, named the *feal*: this is always called *flaying the moor*. For this purpose an ancient description of spade is used, the shaft of which is long and light, while the iron-plate at the bottom of it is of a different shape, and much narrower than that which distinguishes the common spade of England and Scotland. There is one man, who, with this implement, makes a ditch seldom wider than two feet, while another is employed in disengaging the feal that has been cut, which he throws on the delver's right hand-side, in the most slovenly manner. When the moor is thus *flayed*, an ancient Scandinavian implement of husbandry is used for casting the peats, named a *tuskar*: its shaft is rather longer than that of a common spade, while to the bottom of it is affixed a sharp iron-plate, styled a *feather*, which projects from one point seven inches, and from another little more than an inch. Thus, when the Shetlander, in wielding his tuskar, pushes down the feather into the moor in a perpendicular direction, a corresponding shape and size is given to the peat that is cut; he then, with the greatest activity, lifts up each portion as it is severed, and while it rests upon his tuskar, throws it abroad on his left hand-side, or piles it in such a manner that proper intervals may subsist for the admission of air. The ditch is dug very narrow, and its depth rarely extends beyond the depth of two peats. When this labour is finished, the peats appear in loose slovenly heaps, (being but seldom deposited at the bottom of the ditch,) with the verdant surface upwards, so that vegetation is continued. With regard to the length and direction of the excavations, they are governed by no rule, the tenant having the unrestricted liberty of making what devastation he chooses upon his pasture. Often, as Mr. Shirreff in his Agricultural survey has remarked, the cuts are at right angles across a declivity, so as to catch all the surface water that runs down the slope, and to prove traps for drowning sheep; or not unfrequently the water bursts over the lower sides of the trenches, and converts the ground, for a considerable distance, into an unsightly gulley. In the course of a fortnight or three weeks after the peats have been cast, they are set up on one end, that the drying may be completed: but the close of the process is in the middle of the summer, when the Shetlanders build up their peats in large stacks near the place where they were dug, or, by means of the little shelties of the country, carry them home.

There is one practice which occurs in a few parts of Shetland, particularly in Bressay, that deserves particular notice. When a moss is but one peat deep, the inhabitants, after obtaining from it their fuel, lay the sods with which the peat was covered in a fine clay bottom, press them down with the feet, and derive from them good crops of grass, or, when broken up, good crops of corn.

Manure.—The manure intended for tillage is a midden, consisting of dung, of heather that had been cut up for litter, of sea-weed, and of earth or dry decomposed moss, named *Duff-mould.* This compost, which has been known from the remotest antiquity, is an object of such importance to the Shetlander, that the ill-judged sacrifice which he often makes in order to obtain the ingredient of earth, might be considered as exaggeration, if it were not attested by a committee of the Shetland Agricultural Society, appointed in the year 1818 to adjudge the premiums for a certain district of the country: they state, that they were concerned to observe the extent to which the pernicious practice, too common all over the country, is carried, of cutting up the uncultivated grounds in the neighbourhood of the principal farms for manure; that it happens unfortunately to be the most improvable ground which is thus sacrificed, and that one man was observed to have destroyed his very town-maills for this purpose, when the earth was not more than two or three inches deep.

When manure is to be carried to the fields, a klibbar or wooden saddle, of the form which has been described, is fixed on the back of each shelty, to which cassies or straw-baskets are appended. Sometimes the manure is carried to the land by women.

Infield and Outfield.—The arable land generally preferred for culture is described as sandy, or composed of a mixture of clay and gravel that approaches to a soft loam; but often it consists of a black mould resting on clay alone, or on clay and sand. It is usual to give to land a distinction that was no doubt introduced into the country by the Scottish settlers; that is, into *infield* and *outfield.* In Scotland, the land lying near the homestead was kept for successive years in tillage, and, under the name of *infield*, received all the manure, mixed with earth, which the farm afforded. Thus also in Shetland many inclosures near the houses have been dunged every year, and have been sown in the end of April with bear and oats for more than half a century, without ever lying fallow, or having produced a different kind of grain; but the Shetlanders have not imitated certain Scottish districts, in allowing no manure to any part of the land but that which was properly *infield.* In Perthshire, for instance, any portion of land which lay in a valley at a distance from the house, and was sufficiently free from stones, was, under the name of *outfield*, alternately kept in corn, and natural ley or weedy wastes, without receiving the smallest return of manure, except that which was afforded by cattle, when it was used for the purpose of folding. But the outfield of the Shetlander, which is often mossy, and seldom drained, has long received each year a portion of dung, mixed with duff-mould, earth, or sea-weed. The ground is slightly harrowed; it is then sown in the end of March or beginning of April with black oats. The dung which has been carried out to the land during the winter is afterwards applied to the surface of the sown ground, and not being incorporated with the soil, wastes away by the action of the sun and rain. During the next season the outfield lies fallow; and thus in alternate years it is under tillage and in ley. Sometimes the ground is two years laboured, and lies two years ley. It has been also long customary in the country to adopt in the outfield a mode of marking out beds for oats that resembles the lazy-bed way of Scotland, incidental to the cultivation of potatoes. Moss-earth, sand, &c. are thrown up from an adjacent ditch, and upon this substance oats are sown, which thrive remarkably. In the year 1750, potatoes were introduced for the first time into Shetland, when it became customary to obtain from the infield, in alternate years, a crop of this vegetable; and at the present day, oats, potatoes, and bear, are not unfrequently produced in succession. Of late years cabbages have been much less cultivated, their use as a food being superseded by potatoes.

Ploughing.—The Shetland plough is single-stilted, like one that is represented by Olaus Magnus as common to northern nations. A crooked piece of wood bent to a right angle forms the beam of the plough, which has a length of six feet, and a height of two feet and a half; the single stilt at the top of it consists of an oak stave seven feet long. Through the lower end of the beam a square hole is cut, for the introduction within it of a piece of oak about 22 inches in length, named the Mercal, to which is affixed the sock and sky. The coulter stands nearly perpendicular to the sock, while a wedge driven below or above the mercal regulates the depth of the furrow. A slender machine of this sort, which one man may lift with ease is driven by four oxen abreast. Two yokes, joined by a double rope, are laid on their necks; a large one on the two outermost animals, and a small one on the two innermost. The draught or chain with which their necks are bound to the plough is from 18 to 24 feet long. With this strange instrument two labourers take the field. The holder of the plough stands on the left of the pliable stilt. The driver or *caller*, as he is named, goes before the oxen, walking backward: the sound of his whip sets the cattle in motion: the holder of the stilt lies on with his side: the earth is turned over; the work is executed to admiration, until a large stone encounters the coulter, and then crack go the joints of the framework. All hands are now pressed into service for repairs, and the plough is again set to rights. A lash of the caller's whip again causes the beasts to resume their tardy pace. Every thing is carried on smoothly until a stiff furrow appears, when another impediment takes place. It is now necessary that the stubborn glebe should be broken down; this is accomplished: the labour of the plough is again resumed, and, by the help of heaven, is at length happily accomplished. Such being the operation of this primitive machine, every antiquary must regret that an implement of this description, elucidative of the earliest state of Scandinavian agriculture, is going fast out of use, chiefly owing to the innovating spirit of the Shetland New Agricultural Society.

But for turning up land, the plough has been often laid aside, and the ancient, slender, and long-shafted spade of Shetland, which has a blade a quarter of the breadth of the common garden spade of Scotland, and a convenient projecting piece of wood for the application of the foot, is in much greater requisition, being indeed well enough adapted for the rugged and stony ground of the country.

Reaping and Harvest.—In August, after the expiration of the ling fishery, the natives first begin to cut heath, mixed with various plants of the hills, for winter fodder. The grass is mown with a small scythe, of a construction peculiar to the country. So severe is the climate, that the corn harvest often begins very late. Instead of the crop being in the yard in the middle of September, this event rarely occurs before the end of October or even November. The corn is then cut down with a very small sickle, the sheaves are put up in small *stooks* until dry, carried into the corn yard, built in large stacks, taken into the barn when wanted, threshed with a flail, winnowed and dried on kilns.

The causes which prevent the Shetlanders from reaping the produce of their labours are various. The swine of the country, wild boars in miniature, a race of little, ugly, brindled rangers, not much larger than terriers, are too often suffered to roam abroad, and destroy the fruits of the earth. The imperfect dikes, constructed of turf or stones, easily yield to these animals, their assaults being supported by wild shelties and sheep. In the south of the island, rabbits have continued to increase the desolation of the sand-flood, which there prevails. Instead of the growth of plants, which have a tendency to resist the escape of the levigated particles of the subsoil, being encouraged, the reeds, which grow among the sand, are for the laudable purpose of making besoms, still dug up by the roots; numerous herds of swine are allowed to roam at large, and dig in the sand, while rabbits even meet with a hospitable protection.

But, unfortunately, the elements militate most against the Shetland husbandmen. Heavy gales, combining with the spray of the sea, often destroy the crops in a single night. "When the winds blow with great force," says a writer on Shetland, "the surges rise in proportion, dashing violently against the rocks. The white salt froth which is forced up against the highest promontories, mixes with the air in circulation, is carried over lands under cultivation, falls, as it passes, on the corns, dries and hardens upon them, by which its farther growth is impeded, and the most sanguine hopes of the poor farmer destroyed. The straw even, as well as the hay, becomes unfit for any purpose in husbandry." From this cause, a very distressing winter famine has not unfrequently occurred.

Mills.—The ancient quern is still used in Shetland. A hand-mill of this kind consists of two stones about 21 inches in diameter, that rest on a kind of table. Near the edge of the upper stone, is a handle which the grinder, (generally a female of the house,) seizes and turns round with a sort of centrifugal movement, whilst the left hand is employed in supplying with corn a hole in the centre. The meal then flies outwards, and drops from between the stones on the table, when it is every now and then scraped together and taken away.

Water-mills, probably as old as the time of Harold Harfagre, likewise exist. The innumerable slender rills that pay their tribute to each voe, occasionally serve to supply some small mill, the presence of which is signified by a low shed of unhewn stones, that stretch across a diminutive streamlet, over which it is possible in many places to stride; compared indeed with a water-mill of Scotland or England, the grinding apparatus of Shetland seems designed for a race of pigmies. The millstones are commonly formed of a micaceous gneiss, being from 30 to 36 inches in diameter. Under the frame-work by which they are supported, is a sort of horizontal wheel, of the same diameter as the millstones, named a *Tirl*, which consists of a stout cylindrical post of wood, about four feet in length, into which are mortised twelve small float-boards, placed in a slanting direction, or an oblique angle. It has a pivot at its under end, which runs on a hollowed iron plate, fixed on a beam. A strong iron spindle, attached to the upper end of the tirl, passes through a hole in the under millstone, and is firmly wedged in the upper one. A trough conducts the water that falls from the hill upon the feathers of the tirl, at an inclination of 40° or 45°, which, giving motion to the upper millstone, turns it slowly round. To the hopper that surmounts the upper millstone, there is a log of wood fastened, which, striking upon the uneven upper surface of the stone, shakes this repository for the corn, and makes it come out, while too quick an escape is checked by a device for lessening the size of the aperture. But sometimes there is no hopper at all, and a man patiently feeds the mill with his hand.

Bread.—From the oats and bear raised by the natives, a very coarse and ponderous bread is made; but sometimes the grain, after it has been ground by the quern, is passed through a sieve with much care, and is then formed into small cakes, very round and thick, named *Broonies.*

Sheep.—The wild sheep of the country, of true native breed, resemble in their form, their nimbleness and fleetness, the argali, or wild sheep of Siberia. They are celebrated for their small size, and known by naturalists under the name of the *oves cauda brevi*, that at the present day range among the mountains of modern Scandinavia and Russia: in very few places are the Shetland sheep mixed with a Northumberland breed. Their colour is exceedingly various, being grey, black, dunnish brown, white, or they are streaked and speckled in the most curious manner with a combination of various tints and shades. Besides the distinctive character which they possess, from the shortness of their tails, their horns also are very small. In summer, they collect from the pastures that kind of food which the natives still designate by the ancient Scandinavian term of *Lubba*, expressive, in the original sense, of coarseness or roughness. Lubba consists of those common productions of the hills which are found where heath is absent; thus it comprises several kinds of Carices, of *Nardus stricta*, *Eriophoron* or cotton-grass, which is the food of sheep in spring, and of other plants. *Burra*, which is the provincial name given to the *Juncus squarrosus*, serves the animals during the winter. But besides these plants, the *Erica vulgaris* and *tetralix* are the last resources. The sea also affords provision for the wild inhabitants of the Shetland scatholds, and there almost appears to be a peculiar instinct, which, in the severer months of the year, prompts them, upon the ebbing of the water, to fly to the shore, where they remain feeding on marine plants until the flow of the tide; they then return to the hills. The diseases to which they are subject are as various as in the several districts of Scotland; thus they are afflicted at times with what the Scotch call *braxy*, or an inflammation in the bowels, with the *sturdy*, or water in the head, with blindness, from which they frequently soon recover, and with the rot. About forty or fifty years ago, the scab was unfortunately introduced into the Mainland, and proved very fatal, reducing the number of these animals in some places to a third. The natural enemies of the young lambs are eagles (named Ernes), ravens, hooded crows, and the black-backed gull. Of these, the sea-eagle *(Falco ossifragus)*, and the ring-tailed eagle *(Falco fulvus)*, are the most formidable: nor is the *Vultur albicilla*, or white-tailed eagle, unknown as an assailant of the Shetland pastures. Other formidable invaders of the flocks are the swine, which are suffered to roam uncontrolled over the scatholds, and to dye their tusks in the blood of young lambs when just dropped.

The sheep are allowed to run wild among the hills during the whole of the year, herding and housing being almost wholly unknown in Shetland. No food is provided for the poor animals during deep falls of snow, nor is there any friendly shepherd to drive them to some *buill*, or dry place of shelter, where the lives of numbers of them might be preserved. Upon the approach of a storm, a sense of common danger causes them to congregate for self defence beneath the shelter of some rock on the sea shore, where they protect themselves from the cold, by the warmth which arises from their bodies during a crowded state; or, if they are covered with snow, hunger impels them to tear portions of wool from each other's backs.

Whenever it is requisite to catch any sheep, they are hunted down with dogs, trained for the purpose, which Wallace, the historian of Orkney, describes as a sport both "strange and delectable." When a flock is in sight, the Shetlander seizes hold of his *had-dog*, (the ancient Scandinavian name for a sheep-dog,) and points out to him a particular sheep. The dog then bounds after his prey: the flock are immediately alarmed, but soon perceiving the particular individual that is the intended victim, they restrain their flight, and allow the pursuit to be uninterruptedly confined to one object of selection. The poor animal is then chased from hill to hill, until he falls into the power of his pursuer, who is taught to seize him by the foot, the nose or the ear; or perhaps he perishes by tumbling over some precipice, where he is either dashed to pieces upon the stones, or falls into the sea.

As the sheep of one scathold, island, or parish, constitute a promiscuous flock, which may belong to more than a hundred individuals, it is remarkable that more frequent disputes should not have arisen, respecting the rights of possession. No property of this kind was ever secured without the means of had-dogs, it was therefore a proper regulation that none of these animals should be kept in secret. The next object of the ancient legislators of the country, was to see that each dog which might be kept to take sheep, was under proper control, and that he was not what was named a *running dog*, whom the old acts of Orkney characterized as "a dog that runs frae house to house, or through the country chasing the neighbours' sheep;" such a dog would be not only prompt to seize a sheep for his master, but would have little hesitation in providing mutton for himself. But since this act was framed, a sort of demoralization has taken place in the character of the canine race of Shetland,—and it would be difficult to say, at the present day, what dog was not a *running dog*. Mr. Shirreff, in his agricultural survey of the country, has complained with great justice, of a rapacious ranger of this kind that came under his observation, who, without any order from his master, would break off at the first unfortunate sheep that he saw, throw him down, give him a good biting, and then return, unchided for his cruelty to his owner, who seemed to consider the treatment as a matter of course. "The fact is," adds the narrator, "that there is so little profit arising from sheep stock, in the present state of landed property, compared with fishing, that the land-owners and tacksmen do not put as much value on a sheep, as in Great Britain on a hare."

When sheep were considered of more value than they are at present, it was of great consequence that no wild or *scar* sheep should be at large in any particular district, which might have the tendency of dispersing a flock. But, at the present day, most of the sheep of the country are so wild, that the old distinction of scar sheep seems to be nearly lost; and as summer herding is almost unknown, these animals are by no means in a progressive state of tameness.

Again, as the seizure of sheep took place by means of dogs, it was necessary for the preservation of individual property, that no capture should be private. Every proprietor in claiming his share of a promiscuous flock, had a particular mark of his own, that was formed by various kinds of incisions, which were inflicted on one or both of the animal's ears; these received such names as a shear, a slit, a hole, a bit out of the right or left ear, before, behind, or from the top. In this way an infinite variety of private marks was devised, but none of these could be lawfully used without the sanction of the bailiff of a district, or civil officer, whose duty it was to insert in a public register a descriptive account of all the tokens which any individual wished to adopt, for the recognition of the particular share which he had in a joint stock of sheep. It was, therefore, a proper regulation, that the marking of sheep should be a public act, and that no property could be thus claimed, but in the sight of a whole district. The period appointed for marking lambs, was when all the proprietors for flock were assembled for the purpose of *rueing*, or tearing off with the hand the wool from sheep, after it had naturally begun to loosen: this was about the middle of May, or near midsummer. The time of marking and rueing is still publicly proclaimed, and on the day fixed, all the men of a district turn out, and drive their common flock, without any preparation of washing, into rude inclosures, named *punds* or *crues*. If the *punding* be delayed too long, the sheep become so wild that they are hunted down and taken by dogs: but when at last they are secured within the *crues*, the civil officers (who were in former days the bailiff and ranselmen of a district) appear as arbiters of all disputes. Each owner now searches the crue for his property, which the civil officers confirm by their register, and also claims the lambs that are produced from the particular stock that he possesses, in order that his right to them may be secured by a proper ear-mark. At the same time the general *rueing* begins; the proprietor seizes hold of each sheep in turns, and, disdaining the use of shears, pulls up the wool by the roots from the struggling animal's back; and if the fleece has not begun to naturally loosen, which is too frequently the case, the operation is attended with excruciating pain. Such a cruel mode of fleecing, which is of true Scandinavian origin, is at the present day retained in Iceland, as well as in Shetland.

Thus it is shown, that no claims of individual property among sheep could, by the ancient laws of Shetland, be sanctioned, if made in secret. According to the old act, if any person use a sheep-dog, and run therewith after his own sheep unaccompanied; if he mark, rue, or take any home without showing the mark, or if he kill a sheep without first showing the mark to a ranselman, "or other honest man," he was liable to be fined, and, for a repetition of the offence, to be punished as a common thief, and prevented in all time coming from keeping a sheep-dog. It is a pity that, in reference to the undivided state of the scatholds, the salutary tendency of these good laws has not been perpetuated. It has been remarked by Mr. Shirreff, that the Shetlander, who may possess the best sheep-dog, is by repute the greatest sheep-owner in Shetland; and that thieves are greater enemies to the sheepstock than either defect of food or the inclemency of the weather:—he produces as an example, some natives of Yell, who, for several years, had contrived to secure for themselves, on an average, two sheep each week.

The carcass of the Shetland sheep is very small, being said not to weigh more than thirty pounds. The flesh is peculiarly sweet, and may rival in flavour the best Welsh mutton, that is so esteemed in England. But, owing to the crooked policy of proprietors leaving none but the worst lambs, which are unacceptable to the table, for breeding rams, the race of Shetland sheep has been long suspected to be in a state of degeneracy. The wool is short, yet very fine From the amount of the tithes paid in this commodity to the Pope, so early as the 14th century, it has been supposed that the breed of sheep in this country was much greater in ancient times than at the present day. Their wool, which was manufactured into the coarse cloth, named wadmel, afforded the means this ancient colony of Norway possessed of paying the tribute which was due to the King of Denmark, under the title of *scat*. No walk-mills existed, and the web was sometimes thickened by the hands and feet, and at other times it was securely spread along the bottom of a narrow passage among the rocks through which the tide ebbed and flowed, so that the action of the sea, which, in such pent up channels was much increased, might *walk* or full the cloth. When thus prepared, the fabric acquired the name of *Tuvaca-thor*. Early in the last century, the Earl of Morton ordered a walk mill to be built, but the manufacture of wadmel was then much on the decline. There is at the present day, a considerable quantity of white woollen cloth made for home use, which supplies the place of linen.

The chief use to which the Shetland wool is applied is for the stockings and gloves that are knit. The fleece of the sheep, which is remarkably soft, has been wrought into stockings so fine, that they have been known to sell as high as 40*s*. per pair. The price of the most common quality, however, is about three or four shillings, whilst they are manufactured so coarse as to be worth no more than fivepence or sixpence. The knitted covering for the head, resembling a common double nightcap, which the master of a family wears, is an object of the Shetland manufactures. The variegated and fantastical colours which it displays are produced by native dyes. The lichen *Tartareus* yields a lit or dye, that was formerly an object of commercial notice, named Korkelit; it is scraped from the rocks after a fall of rain, reduced to a powder, steeped for many days in stale householdley, and kneaded into balls of the weight of a pound and a half, which are dried. When boiled with cloth, it communicates to cloth a reddish purple colour. The lichen *Saxatilis* (provincially named *Old man*,) when treated partly in the same way, yields a yellowish or reddish brown colour. The lichen *Parietinus* (named by the Shetlanders *Scriota*) dyes cloth of an orange colour. The lichen *Omphaloides* is also occasionally used for the purpose of affording a brownish or blackish purple colour. From a collection of plants, among which is the marygold, a yellow colour is procured. A good black is extracted from the mossy earth of the country, when found much impregnated with bog iron ore. Another sort of woollen cloth manufactured is expressed by the term *Kiverins*, or *coverings* for the beds of the peasantry. These are composed of very coarse materials. Sometimes they form a ground, into which different coloured worsteds are sewed, so as to display various figures of more or less beauty, according to the taste or ingenuity of the operator. Manufactures of this kind are then used for rugs and hearth-covers; when intended for better coverlids, the figures of them are, with a view to warmth, produced by thicker threads, the thrums of which are left about two inches long. The last use for which kiverins are designed, is for saddle-cloths; these are placed under a klibbar, when the shelty is mounted by a female rider. The skins of the Shetland sheep are in requisition, for the purpose of affording the fisherman a sort of surtout, that covers his common dress. The *tormentilla erecta* has been long used in the process of tanning.

Pasturage.—Regarding pasturage little need be remarked. The best pasturages are to be found where limestone prevails. Natural red and white clover, with ryegrass and the *Vicia Sepium* may be observed growing spontaneously in many parts of Scotland. Many of the islets of the sea, named holms, afford a very fine succulent pasture for black cattle, and for sheep destined for the table, such spots being indeed the chief places where they are fattened. So great indeed is the value attached to these holms, that, by the ancient laws of the country, trespasses on them are punished with severity.

The famous holm of Noss deserves particular notice. This holm, which is about 500 feet in length, and 170 in breadth, rises abruptly from the sea in the form of a perpendicular cliff 160 feet in height. The chasm which intervenes between it and the no less precipitous banks of Noss is 65 feet across. The original temptation to reach the holm was to acquire possession of the eggs of the numerous sea birds by which it was annually frequented. A fowler succeeded in scaling the cliff, bearing with him two stakes which he fixed into that part of the bank which was nearest to the opposite rock. When this was achieved, a firm cordage was applied to it so as to form the medium of transport from bank to bank. In the next place an oblong box named a cradle was contrived, through the extremities of which two holes were made in order to allow ropes to pass along each of its sides. By this means, the machine was properly slung. The cradle is large enough to contain one man and a sheep; and as there is a slight descent from the cliff to the holm, the man easily moves forward, and, by means of the lateral cords, regulates the celerity of his conveyance. In returning, he is assisted by persons stationed on the opposite bank, who draw him up by means of a rope that is for this purpose attached to the cradle.

Kelp.—Very little kelp is produced in Shetland. For the preparation of it, a hole about six feet long, and about half the dimension in breadth, is dug in the earth for the reception of the sea-ware, and when the ignited matter acquires a glutinous consistency, it is stirred up with a rake, and then allowed to cool.

Shetland Agricultural Society.—The institution of this very useful society took place a few years ago, and a better system of farming may be in time expected. The attention of the gentlemen of the country is laudably directed to a division of commons, as the groundwork of all agricultural improvements; but in the meantime, the premiums that are given for the growth of turnips, which are found to succeed remarkably well,—for the breaking out of waste ground,—for the improvement of live stock,—and for the cultivation of artificial grasses,—already promise the most beneficial results. Not long ago leases were unknown; and although annual tenants still continue to be the greatest portion of land-cultivators, yet much longer terms may in many parts of the country be easily procured.

V. Fisheries of Shetland.

After having described the husbandry of Shetland, we shall next introduce the Shetlanders to our readers as fishermen, which is the true character of this remarkable people. But first we shall notice the construction of their boats.

Boats.—The Scandinavian origin of the natives is illustrated in the form and lightness of their boats or yawls, the planks of which are still imported from Norway, so modelled by the hands of the carpenter, that, when they arrive in Shetland, little more labour is required than to put them together. These boats are generally about eighteen feet in keel, and about six in beam; they carry six oars, and are furnished with a square-sail. Their extreme buoyancy, and the ease with which they cut the waves, are the circumstances insisted on by the fishermen, as rendering their construction particularly adapted to the stormy seas upon which they are launched. Many of the boats are, however, less in size, being adapted only for four oars.

Fishery for Sillocks.—The annunciation of a fine Shetland evening is always expressed by numerous boats covering the surface of each bay, the crews of which are engaged in angling for the small fry of the coal-fish, or *gadus carbonarius*, known in Shetland by the name of Sethe. These swarm in myriads within the numerous creeks and sounds of the Northern Archipelago. They first appear in May, scarcely more than an inch long, and in comparatively small quantities, but gradually increase as the summer season advances, when about August they become very abundant, measuring at that time from six to eight inches in length. During this time the fry are distinguished by the name of Sillocks. About the month of March ensuing, they are found to have grown to the length of about fifteen inches, when they acquire the name of Piltocks. After this period they thrive very fast, attaining the ordinary size of the cod-fish: a profitable fishery then takes place of them in deep tideways, under the name of *Sethes.* Although the fry of the sethe frequent all parts of the bays, yet the fishermen assert that their favourite resort is among the constant floods and eddies which occur near sunken rocks and bars, that are alternately covered and laid bare by the waves. The fishery for sillocks or piltocks is, therefore, occasionally fatal to the more adventurous boats, which, in quest of them angle in such perilous situations. But, besides frequenting tide-ways and currents of all kinds, these small fry appear to covet the security of thick plantations of sea-ware, within the shelter of which they are protected from the keen look-out of their natural enemies of the feathered race.

There is, probably, no sight more impressive to the stranger who first visits the shores of Shetland, than to observe, on a serene day, when the waters are perfectly transparent and undisturbed, the multitudes of busy shoals, wholly consisting of the fry of the sethe, that Nature's full and unsparing hand has directed to every harbour and inlet. As the evening advances, innumerable boats are launched, crowding the surface of the bays, and filled with hardy natives. The fisherman is seated in his light skiff, with a rod in his hand and a supply of boiled limpets near him intended for bait, or he occasionally angles from the ledge of a rock. A few of these limpets are carefully stored in his mouth for immediate use. The baited line is thrown into the water and a fish is almost instantaneously brought up. The finny captive is then secured; and while one hand is devoted to wielding the rod, another is used for carrying the hook to the mouth, where a fresh bait is ready for it, in the application of which the fingers are assisted by the lips. The same manual and labial routine goes on with remarkable adroitness and celerity, until a sufficient number of sillocks are secured for the fisherman's repast. But, in any season of the year, the limpet bait may be superseded by the more alluring temptation of an artificial fly. The rod and line are then handled with a dexterity not unworthy the fresh-water talents of a Walton or Cotton. It may also be of some interest to "brothers of the angle," as Isaac Walton calls his companions, to learn that the Shetland fly, to which sillocks rise, is rarely intended to represent any particular species observed in nature. The Shetlander assures us confidently, that two wings are necessary for the insect, the fish distinguishing nothing more. The inference is, that there is an intellectual gradation among the finny tribe, and that the fry of the sethe are not so clear-sighted as the more wary and knowing inhabitants of pellucid trout-streams. For the construction of the bait, the white feather of the common gull, or of the goose, is sometimes used. But the fibres of the tail or back fin of the dog-fish, which, when cleaned, shines like silver, is preferred to any other kind of materials, being considered by the fishermen as particularly enticing. The fly is attached to a white hair line, and when this cannot be procured, to a brass wire.

So easily are captures made of these small fry, that while active manhood is left at liberty to follow the more laborious occupations of the deep water fishery, or to navigate the Greenland Seas, it is to the sinewless arm of youth, or to the relaxed fibres of old age, that the light task is consigned of wielding the sillock-rod.

The lavish abundance in which the fry of the sethe visit the inlets of Shetland, affords sufficient matter for contemplation to the reflecting mind. Among islands, the severe climate of which is too often fatal to the labours of husbandry,—where the reduced rate of labour, resulting from the debased political state of the country, precludes the purchase of meal at a cost much above the usual price in commercial districts,—under such circumstances, what is there that can possibly render a few insulated rocks capable of supporting a population of more than 20,000 souls? The reply is not difficult. That kind Providence,

"—————who pours his bounties forth
"With such a full and unwithdrawing hand,
"Thronging the seas with spawn innumerable,"

has not neglected the obscure shores of Hialtland. Amidst the occasional visitations of famine, the severity which overwhelms in despair the commercial population of the south, prompting to every act of civil insubordination, the Shetland peasant has only to launch his skiff on the waters which glide past his own dwelling, and he finds that a bounteous supply awaits him at his very door. The fry of the sethe, in a scarce winter, has constituted the breakfast, the dinner, and the supper of the Shetland peasant. The livers are also converted to an important use; being collected in a tub, they are boiled for oil, and the overplus is sold. "Thus," says a female writer of Thule (Mis Campbell) with much eloquence, "the two articles most required in a climate like that of Shetland, have been abundantly provided,—these are fire and light. The natives have for their labour, as much fuel as they can consume. Whatever wants may be in a Zetland hut, their is seldom or never a good fire wanting. The fish which they catch, almost at their doors, supply them with the means of light. The cold and darkness of their long winters are thus mercifully robbed of their terror; and in the mud-walled cottage of the Zetlander, the providence of God is as conspicuous, and as surely felt, as in those favoured lands which flow with milk and honey, and where the sun shines in all its glory."

Cole fishery.—The *gadus carbonarius*, cole-fish, or Shetland sethe, is the sillock full grown. The fish is of a large size, sometimes attaining the length of three feet, having a small head, sharpened snout, and a lower jaw exceeding the upper in length. Being a great frequenter of tide-ways, the rousts of Sumburgh and Scaw, where conflicting tides meet, offer for him attractions of no common kind. Cole-fish are here found in great numbers; while in quest of them, the dauntless Shetlander launches his light skiff among the white waves of contending tides. The manner in which the fishery is conducted, is well described in a pamphlet, published A. D. 1787, entitled "Considerations on the Fisheries in the Scottish Islands."

"The yawl contains three and sometimes four men, for the cole-fishery. Each of the boats is rowed by two men; the others are placed one at the stern and another at the head, with floating lines thrown out on the tide-side; the hook being baited with the whitest part of the belly of the cole, cut nearest to the size of a herring. The rowers direct the boat as close to the edge of the broken water as they can with safety; for were they to fall into the tide they must perish, as no assistance could be given them. They exert their utmost strength on this occasion to keep the hook always on the surface, whilst the fishers fix their eyes on the bait, as the more the water is raised by the force of the tide, the more successful the fishing proves, as the deceit is better concealed. Whenever the coles come to the surface of the water, they are then in quest of herrings; and if the fishers find any in their stomachs, they deem it a treasure, and apply small pieces of it over the other bait. When the tide is run, and the fish follows, he drags for it by putting to the line a lead or *sinker*, which is commonly a pound and a half weight; this being let down into the water to the depth of twenty fathoms or more, he hauls it up with all quickness possible. Thus, the deception takes place most powerfully; and the fish, aiming at the herring in motion, and seemingly running away, is the more easily taken. This species always plunges deeper into the waters, in proportion as the tide wears weak."

The taste of the cole-fish, when in a fresh state, is not relished; but, when cured for sale, is better. It is sent to the Scotch market, where it sells cheaper than cod or ling.

Ling-fishery.—This is the great fishery of Shetland. It has been explained, while describing the causes and nature of fishing tenures, that the landlord allows his yearly tenant to be in debt to him for the boats and fishing lines necessary for the taking of ling, but requires from him the obligation, that all the fish which he may take during the customary season, shall be sold to him at a stipulated rate; which complicated relation of landlord and tenant has ever since prevailed in the country.

It is well known that the ling frequent the deep vallies of the sea: the cod resort to the high banks. Another fish caught along with the ling, and resembling it, is the *gadus brosme*, or *Torsk*, commonly named *Tusk*: but it does not obtain the same length. In this fishery, cod is also taken, though sparingly.

The ling fishery commences in the middle of May, and ends on the 12th of August. The fisherman then equips himself in his boat dress, which is not a little striking. A worsted covering for the head, similar in form to the common English or Scotch nightcap, is dyed with so many colours, that its bold tints are recognised at a considerable distance, like the stripes of a signal flag. The boatmen are also invested as with a coat of mail, by a surtout of tanned sheep skin, which covers their arms, and descends from below their chin to their knees, while, like an apron or kilt, it overlaps their woollen *femoralia*:—for with the latter article, it is needless to observe, the Shetlander is better provided than the Highlander. This sheep-skin garb has generally an exquisite finish given to it by boots of neat-skin materials, not sparing in width, reaching up to the knees, and altogether vying in their ample dimensions with the noted ones of Charles the Twelfth. A nobleman, who visited Shetland a few years ago, was indeed so struck with the fishing-garb of the natives of the place, that he afforded it a place in his museum, at no remote distance from kindred illustrations of the habits of the Esquimaux or of the New Zealanders. This leathern dress is certainly of Scandinavian origin: a similar one is still worn in the Isles of Feroe, and Bishop Pontoppidan describes the same as being common in his time among the peasantry of Norway.

For the prosecution of the ling fishery convenient sites on the coast are selected. The fishermen are allowed by law to build for themselves huts on any site which may be uninclosed, uncultivated, and at a distance of not more than 100 yards from the high water-mark. These are severally constructed of rude stones, without any cement, being no larger than is sufficient to contain a boat's crew of six men. They form the roof of thin pieces of wood, on which they lay turf; they then strew a little straw upon the ground, in order to snatch from their severe labours a short repose. One of the most noted of these fishing stations is a narrow isthmus of low marshy land, that connects the peninsula of Feideland to the Mainland. Here are interspersed, with all the disorder of a gypsy encampment, a number of these savage huts, named *summer lodges*, and in the centre of them is a substantial booth, used by a factor for curing fish. Feideland is a place possessing no little interest; a remarkably busy scene being presented by the numerous crews sailing to the Haaf, or returning from it laden with fish. Some men are busily engaged in weighing the stock of ling, cod, and tusk, as it is brought in to the factors; others in spreading their lines on the rocks to dry, or in cooking victuals for their comrades, who are employed on the haddock grounds, or in brushing, splitting, and salting the fish that are brought to the door of the booth.

The ling fishery will be now described as it is prosecuted at THE HAAF.

The *Haaf* is a name applied to any fishing-ground for ling, cod, or tusk, on the outside of the coast. The men employed are from 18 years of age and upwards. On the 25th of May, or on the 1st of June, the fishermen repair to their several stations. They either endeavour, with rod and line, to procure for bait the fry of the cole-fish, of the age of 12 months, named piltocks, or they obtain at the ebb muscles and limpets; and then going out to sea six miles or more, lay their lines for haddocks, and after obtaining a sufficient supply of these fish, reserve them for bait. When piltocks or haddocks cannot be procured for bait, which is a rare circumstance, halibut, cod, tusk, and even ling are substituted.

The Feideland Haaf being 30 or 40 miles from land, the fishermen endeavour to leave their station in the morning of one day, so as to be enabled to return in the course of the day following. And if, owing to boisterous weather, they have suffered long detention in their lodges, the first boat that is launched induces every weather-bound crew to imitate the example; it is therefore no unusual circumstance to see, in a fleet of yawls, all sails set and all oars plied nearly at the same instant of time. When, after a tug of 30 or 40 miles, the crew has arrived at the Haaf, they prepare to set their *tows*, which is the name by which they designate the lines that are fitted with ling hooks. Forty-five or fifty fathoms of tows constitute a *bught*, and each bught is fitted with from nine to fourteen hooks. It is usual to call 20 bughts a *packie*, and the whole of the packies that a boat carries is a *fleet of tows*. Thus, while a boat in the south or east of Shetland carries only two or three packies, a fleet of tows used on the Feideland Haaf amounts to no less than six, these being baited with seldom less than 1200 hooks, provided with three buoys, and extending to a distance of from 5000 to 6000 fathoms.

The depth at which ling are fished for varies from 50 to 100 fathoms. In setting the tows, one man cuts the fish used for bait into pieces, two men bait and set the lines, and the remaining two or three row the boat. They sink at certain distances what they call *cappie-stanes*, the first that is let down being called the *steeth*. These keep the tows properly fixed to the ground. When all this labour is finished, which in moderate weather requires three or four hours, and when the last buoy has floated, the fishermen rest for nearly two hours. It is here lamentable to think, that their poverty allows them nothing more for sustenance than oat-meal bread baked, and a few gallons of water.

At length, one man, by means of the buoy-rope, undertakes to haul up the tows,—another extricates the fish from the hooks, and throws them in a place near the stern, named the shot,—a third guts them, and deposits their livers and heads in the middle of the boat. Six to ten wet lings are about a hundred weight, and hence six or seven score of fish are reckoned a decent haul,—fifteen or sixteen a very good one,—twenty scores of ling are rarely caught; but, in such a case, garbage, heads, and small fish, are all thrown overboard, nor can these lighten the boat so much as that she will not appear, according to the phrase of the fishermen, just *lippering* with the water. When all the tows are heaved up, they are deposited in the bow of the boat.

If the weather be moderate, a crew does not need to be detained at the Feideland Haaf more than a day and a half. But too often a gale comes on, the men are reluctant to cut their lines, and too many females have to lament the loss of a husband or of a son at the distant Haaf. The dangers there encountered are the frequent theme of the Shetlander's conversation, and his recital of them beguiles the tedious hours of a long winter's evening.

About sixty years ago decked vessels, named succouring vessels, were employed to obviate these dangers. They accompanied the boats to the Haaf, and gave opportunities to the men to procure refreshment and sleep. But from mismanagement the plan was abandoned.

During the fishing-season there is full employment from the Monday morning until the Friday or Saturday following, but few hours for rest. On the return of a boat from the Haaf, the fishermen are first engaged in spreading out their tows to dry; a part of the men catch piltocks with a rod and line, or procure other kinds of bait at a distance from shore: others again mend the tows and cook victuals for the next day's journey to the Haaf. Owing to all these successive and rapid demands on the time of a crew, their sleep seldom exceeds two or three hours in the twenty-four.

The fish are next conveyed to their destination for the purpose of being dried. A beach, formed by large water-worn pebbles cast from the sea is selected, or, in the absence of this convenience, an artificial beach of the same character is constructed, often at a considerable expense.

The curing and drying of fish is conducted with great regularity. When a boat arrives, the ling, cod, and tusk that have been taken at the Haaf, are in a gutted state, and with their heads taken off delivered by weight to the factor. A *splitter*, as he is called, with a large knife, cuts a fish open from the head to the tail, and takes out half the back bone next the head: he then hands it over to the *washer*, who, with a heath brush, and the assistance of the sea water, clears away every particle of blood. When all the fish are in this way split and washed, they are allowed to drain; after which comes the *salter*, who places at the bottom of a large wooden vat a stratum of salt, and over it one of fish with the skin-side undermost, until the chest is filled with alternating layers, and above all are laid heavy stones to keep the fish under the pickle. After remaining in the vat some days, they are taken out, well washed and brushed in a direction from the shoulder to the tail, and put up in small heaps called *clamps*, in order to allow the water to drain off. The fish are next spread out with the skin-side undermost, and exposed to the action of the sun, on a beach composed of round stones, where they are again clamped, and thus alternately spread out, turned, and disposed into piles of a gradually increasing size, until dry. They are afterwards built into a large stack named a *steeple*: and, for the sake of equal pressure, the steeple is again taken down and rebuilt, by which means the fish that were the uppermost in one steeple, are the undermost in another. When the drying, or *pining* as it is called, has been completed, which is indicated by a white efflorescence on the surface, named the *bloom*, the fish are transported to a dry cellar lined with wood, and there piled up closely, or shipped off immediately to a market. A well cured fish is said to be of a greenish-white colour, and when held in the light is translucent.

Shetland Cod Bank.—The Shetland Cod Bank is described as having a breadth averaging from fifteen to twenty miles, as commencing from the west of Westray, in Orkney, and as having been traced in a direction nearly north by west, until Foula lies somewhere about east by south; but it is very doubtful if its extent be known. The depth of the water on the bank is estimated from forty-six to seventy fathoms, its surface being in some places rocky, and in others sandy: it is also covered with buckies, mussels, and razor-fish.

There can be little doubt but that this bank was known to the Dutch and to other early enterprisers who resorted to the Shetland coast; but owing to the languid state of the British fisheries during the close of the seventeenth and commencement of the eighteenth century, it was at last forgotten that ever such a valuable resource existed.

It was long after the departure of the Dutch from the Shetland coast, that the cod fishery, by means of decked vessels, was languidly revived. About ten or twelve years since, a few vessels, from six to thirty-five tons burthen, and carrying from six to eight hands, prosecuted a fishery for cod off the coasts of Shetland, using hand lines, baited with two or three hooks. They seldom went farther to look for fish than the immediate neighbourhood of Foula or Fair Isle; their search was highly desultory, and their success proportionably uncertain; it rarely happened that vessels of only ten or thirty tons, after being employed a week in fishing, returned to their several harbours, like the Dutch doggers described by an old English writer, "so full laden as they could swim."

About nine years ago, one or two fishing sloops accidentally met with the bank: and Dr. Hibbert, who was then conducting his geological surveys of Shetland, instituted particular inquiries relative to its situation, extent, and productiveness, and first communicated the discovery to the public. He remarked that "the discovery of the cod bank had already proved of great importance to the country: employment having been given to many seamen, and an opportunity afforded them, by purchasing small shares of vessels manned by themselves, of investing, to the greatest advantage, the profits of their severe labours in remoter climates; that the improved state of our coasting navigation justified the expectation, that from this source, an economical and nutritious food would eventually come within the reach of the populous districts of our manufacturing counties, the alleviation of whose wants has always actively engaged the attention of the most enlightened of our countrymen."

This prediction has been fulfilled. Before the Bank was discovered, only four or five vessels belonging to Shetland were employed in the cod fishery. Three or four years afterwards no fewer than forty were upon the Bank, who met with the greatest success whenever the weather was favourable; and during the summer of 1826, the following very grateful intelligence has appeared through the medium of the public journals.—"The cod fishery in Shetland this season has been uncommonly successful. In one week lately there were 50,000 cod caught by the vessels employed in the deep sea fishing, and we understand that they have been even more successful since that time. Independently of the fishings carried on by proprietors and their tenants, and in boats, there are at present fifty-seven decked vessels engaged in this department of the Shetland fisheries, giving employment to nearly 600 seamen; and, including these, the persons altogether engaged in it are about 1500 or 1600. The value of the vessel is from L.200 to L.500 each. They belong generally to the fishermen themselves, and were purchased with the fruits of their industry. This branch of the fishery has sprung up within the last twelve years; so that, besides the support which their adventures have afforded to them and their families, and the profits derived from this employment, property in shipping to the amount of nearly L.20,000 has been created by this national and important branch of industry, and is now enjoyed by the Shetland fishermen. A new regulation has been adopted by the fishery board, which is strictly enforced,—that all the fish shall be put in salt within forty-eight hours after being caught; so that only a perfectly good and wholesome commodity can now be brought into the market from that country."

It has been always supposed that the cod prepared in Shetland will maintain its pre-eminence over that of other places. The Newfoundland fishermen are described as exposing their fish, after it has been salted, on standing flakes, made by a slight wattle, and supported by poles often twenty feet from the ground. But the humidity is not near so well extracted from the fish as when, according to the Shetland method, they are carefully laid out upon dry beaches, the stones of which have been, during winter, exposed to the abrading action of the ocean, and are thus cleared from vegetable and animal matter.

The Shetlanders have been very successful in obtaining the prizes offered by the commissioners for the fisheries in Scotland, who offer annually rewards for the greatest quantity of cod taken in vessels of sixteen tons or upwards.

Herring Fishery.—The herring fishery carried on by the Dutch off the Shetland coast was in ancient times an undertaking of the greatest importance. In the year 1633, there were 1500 herring busses, each of eighty tons burden, and a fleet of dogger boats, to the number of about 400, each of sixty tons burden; but owing to wars and other causes these gradually dwindled away, until in the year 1774 the number of Dutch vessels only amounted to 200. The diminution even went on until the fishery scarcely deserved a name; since the last peace some attempts have been made towards its revival.

The commercial intercourse resulting from the annual visits paid by the Dutch greatly assisted the Shetlanders in struggling for a bare subsistence, when the weights and measures of their country had been raised by the hand of power to more than twice their ancient standard.

In 1750, the British government first directed their attention to the herring fishery; and a company incorporated in the same year, entitled, the *Free British White Herring Company*, fitted out vessels that visited the Shetland coasts. They were, by means of bounties, so feebly encouraged by the British government, that the twenty busses which they at first owned gradually dwindled to eight, at which number they stood for several years. The undertaking was eventually given up, after the loss of half a million of money sterling. Lately, the herring fishery of Britain has revived under much greater encouragement, but it is generally conducted off more southerly coasts of Britain than those of Shetland. A few vessels have been fitted out for the purpose from Lerwick; but the herring fishery is by no means a favourite pursuit in this country.

Capture of the Delphinus Deductor, or Ca'ing Whale.—An interesting frequenter of the Shetland seas is the large animal lately named in systems of natural history *Delphinus deductor*, styled by the Shetlanders the *Ca'ing whale*, and by the natives of Feroe the *Grindaqualur*. Adult whales of this kind, which have been often slain on the sands of the Voes in Shetland, seldom exceed twenty to twenty two feet in length. They are of a shining black colour, though frequently white or grey about the belly. The skin may rival in softness the texture of silk. The head is round, short, and thick, having the under jaw shorter than the upper by three or four inches. The eyes are remarkably small; the teeth, which are of the average length of an inch, and of a sharp subconoid form, vary with the age of the animal, being, in the largest, about twenty-four in number. There is a blow-hole near its neck, from which it is able to spout water to the height of a few feet. It has a tail that is cleft and vertical, a short stiff dorsal fin, and two long narrow pectoral fins. The females have two nipples, although they are much concealed by an adipose substance. These whales often appear in a gregarious concourse. We shall quote Dr. Hibbert's account of the capture of these animals: "I had landed at Burra Voe in Yell, when a fishing boat arrived with the intelligence that a drove of Ca'ing Whales had entered Yell Sound. Females and boys, on hearing the news, issued from the cottages in every direction, making the hills reverberate with joyful exclamations of the event. The fishermen armed themselves with a rude sort of harpoon, formed from long iron-pointed spits;—they hurried to the strand, launched their boats, and, at the same time stored the bottom of them with loose stones. Thus was a large fleet of yawls soon collected from various points of the coast, which proceeded towards the entrance of the Sound. Some slight irregular ripples among the waves showed the place where a shoal of whales was advancing. They might be seen sporting on the surface of the ocean for at least a quarter of an hour, disappearing, and rising again to blow. The main object was to drive them upon the sandy shore of Hamna Voe, and it was evident that the animals, with the enemy in their rear, were taking this direction: most of the boats were then ranged in a semicircular form, being at the distance of about 50 yards from them, with the exception of a few skiffs which acted as a force of reserve, keeping at some little distance from the main body, so as to be in instant readiness to intercept the whales, should they change their course. The sable herd appeared to follow certain leaders, who were now inclined to take any other route but that which led to the shallows on which it was intended they should ground. Immediately the detached crews rowed with all their might, in order to drive back the fugitives, and, by means of loud cries and large stones thrown into the water, at last succeeded in causing them to resume their previous course. In this temporary diversion from the shore, the van of the boats was thrown into confusion; and it was a highly interesting scene to witness the dexterity with which the Shetlanders handled their oars, and took up a new semicircular position in rear of the whales. Again the fish hesitated to proceed into the inlet, and again a reserve of boats intercepted them, in their attempt to escape, while a fresh line of attack was assumed by the main body of the pursuers. It was thus that the whales were at length compelled to enter the harbour of Hamna Voe. Then did the air resound with the shouts that were set up by the boatmen, while stones were flung at the terrified animals, in order to force them upon the sandy shore of a small creek; but before this object could be effected, the whales turned several times, and were as often driven back; none of them, however, were yet struck with the harpoon; for if they had felt themselves wounded in deep water, they would at all hazards betake themselves to the open sea. The leaders of the drove soon began to ground, emitting at the same time a faint murmuring cry, as if for relief: the sand at the bottom of the bay was disturbed, and the water was losing its transparency. The shoal which followed struck the shore and increased the muddiness of the bay:—

they madly rolled about irresolute from the want of leaders, uncertain of their course, and so greatly intimidated by the shouts of the boatmen, and the stones that were thrown into the water, as to be easily prevented from regaining the ocean. Crowds of Shetlanders of each sex, and of all ages, were anxiously collected on the banks of the voe, hailing with loud acclamations the approach of these visitants from the northern seas;—and then began the work of death. Two men, armed with sharp iron spits, rushed breast-high into the water, and seizing each a fin of the nearest whale, bore him unresistingly along to the shallowest part of the shore; one of the deadly foes of this meekest of the inhabitants of the sea then deliberately lifted up a fin, and beneath it plunged the harpoon that he grasped, so as to reach the large vessels of the heart. A long state of insensibility followed, succeeded by the most dreadful convulsions; the animal lashed the water with his tail, and deluged the land for a considerable distance: another deathlike pause ensued; throes still fainter and fainter were repeated with shorter intermissions, until at length the victim lay motionless on the strand. The butchers afterwards set off in a different direction, being joined by other persons bent on the same errand. Female whales now appeared, by their hasty and uncertain course, to have been wrested from their progeny, while sucklings were no less anxiously in pursuit of those from whose breasts they had received their nutriment; but, by the relentless steel of the harpooner, they were severally arrested in their pursuit. Others which had received their death-wound soon lined the bay, while a few at a greater distance were rolling about among the muddy and crimsoned waves, doubtful whether to flee, and appearing like oxen to wait the turn of their slaughterer. Wanton boys and even females, in their anxiety to take a share of the massacre, might be observed to rankle with new tortures the gaping wounds that had been made. At length the sun set upon a bay that seemed one sheet of blood: not a whale was allowed to escape; and the strand was strewed over with carcases of all sizes, measuring from six to twenty feet, and amounting to not fewer than the number of eighty. Several of the boatmen then went to their homes in order to obtain a short repose; but as the twilight in this northern latitude was so bright as to give little or no token of the sun's departure, many were unremittingly intent upon securing the profit of their labour, and were engaged in separating the blubber, which was of the thickness of three or four inches. It was supposed that the best of these whales would yield about a barrel of oil; and it was loosely computed that they were, on an average, worth from two to three pounds Sterling-a-piece, the value of the largest being as much as six pounds."

According to the old laws of Shetland, no whale was a droit of admiralty unless it was too large to be drawn by four oxen. One share belongs to the salvers, and another to the proprietor of the ground; the minister claims tithes of the whole. Formerly the bailie claimed the heads. But it is difficult to say how the division is now made.

A few years ago, the carcases of captured whales were allowed to taint the air until they were completely devoured by gulls and crows, but it is an indication of the improved state of Shetland husbandry, that they are now prized by the agriculturist. The bones have been lately exported to England. At Feroe, the flesh of these animals is cured like beef, which it is said to resemble in taste, and is considered as a great dainty; and in the year 1740, a time of great scarcity, it was eaten from necessity by the natives of Northmavine.

Capture of Seals.—The coasts of Shetland swarm with the smaller seals, or *Tangfish*, so named from being supposed to live among the *Tang*, or larger fuci that grow near the shore. These animals, when taken young, are said to be easily domesticated, when they readily assume the habits of the dog, showing attachment to particular individuals of the human species, repairing to the water in quest of fish, and returning to the roof where they have experienced kindness. These seals are often shot, or are enclosed by nets fastened to the mouth of the caves to which they resort, where they are deliberately put to death. In Papa Stour, there is an annual capture of the larger seals, or *Haaf-fish*. To the north of an inlet named Hamna Voe, high cliffs appear, which are shaped by the water of the sea into a continual recurrence of excavations. The most remarkable of these is Christie's Hole, which, when surveyed from the summit of a cliff, appears a cavity of some hundred feet deep, and about 120 feet in length, being situated at a distance of 180 feet from the sea. It can be explored by means of a boat,—a labour that is only to be accomplished in the calmest weather. A large arch first presents itself; and, after rowing through dark vaults, the light of the sun bursts in from the lofty opening above;—here the water is no less than nine fathoms in depth. The boat then pursues its gloomy course through another extensive perforation, which at length expands into an immense cavern, where the light of the sun is wholly excluded. In the innermost recesses, there is a steep beach, which terminates in small dens, where the larger seals, or Haaf-fish, couple, and where the females produce their young, and suckle them, until they are able to accompany their dams to sea. It is customary for two boats' crews of the island of Papa to go to this place, at certain seasons, armed with clubs; one boat only enters, which is provided with candles. The crew attack the seals with clubs, stun them by a blow on the head, and, in this state of insensibility, put them to death. The females boldly step forward in defence of their young; they face their destroyers, and, with their teeth, often wrench the clubs out of their enemies' hands. But the attempt is vain; the walls of these gloomy recesses are stained with their blood, while those who attempt to escape, are met by another boat's crew stationed at the mouth of the cave, when a similar slaughter ensues.

VI. Fowling.

Fowling is still practised in Shetland, though by no means so much as formerly. One island in Shetland is named Fughloe, (*Foula*) or Fowl Island, from the numbers of the feathered tribe that make it a place of resort. On reaching the highest ridges of the rocks, the prospect presented on every side is of the sublimest description. The spectator looks down from a perpendicular height of 1100 or 1200 feet, and sees below the wide Atlantic roll its tide. Dense columns of birds hover through the air, consisting of maws, kittiwayes, lyres, sea-parrots, or guillemots: the cormorants occupy the lowest portions of the cliffs, the kittiwakes whiten the ledges of one distinct cliff, gulls are found on another, and lyres on a third. The welkin is darkened with their flight: nor is the sea less covered with them, as they search the waters in quest of food. But when the winter appears, the colony is fled, and the rude harmony produced by their various screams, is succeeded by a desert stillness. From the brink of this awful precipice, the adventurous fowler is by means of a rope tied round his body, let down many fathoms; he then lands on the ledges where the various sea-birds nestle, being still as regardless as his ancestors of the destruction that awaits the falling of some loose stones from a crag, or the untwisting of a cord. It was formerly said of the Foula man, "his *gutcher* (grandfather) *guid before*, his father guid before, and he must go over the Sneug too."—The high banks of Burra Firth in Urst, and the stacks contiguous to it, are frequented by numberless birds, such as gulls and scarfs; and along with these the lyre, or *Procellaria puffinus*, the Tomnorry, or *Alca arctica*, and the kittiwake, or *Larus tridactylus*. Their nests are annually visited by the nimble and adventurous rockmen, who, for the sake of plunder, land with boats at the foot of the most hideous precipices, which they easily scale, or are let down from the summit of them by means of ropes. The eggs thus obtained, are considered as a great dainty: the carcases of the young birds serve for grosser food, and the feathers form an article of commerce.

VII. Greenland Sea Fishery.

Each year the vessels who go to the Greenland sea fishery touch at Shetland, and procure great numbers of active seamen, who, as boatmen, are held in the highest estimation.

VIII. Commerce.

Commerce.—Before entering on this subject, we may observe, that, with the exception of Lerwick, where there is a manufactory for straw-plaiting, few or no distinct trades are to be found in the thinly inhabited districts of the country; almost every peasant, being the fabricator of his own rivlins and shoes, as well as his own tailor, and his own carpenter. Shetland receives from Scotland and England the materials which she requires for the use of her fisheries, for clothing, &c.

The exports of Shetland consist chiefly of dried fish which are sent to Scotland and Ireland, and from thence find their way to the foreign markets, also a little kelp. The recent discovery of the cod-bank has been the most considerable source of wealth.

The researches of Dr. Hibbert relative to the chromate of iron, have also been a valuable acquisition to the resources of Shetland. This ore is of commercial importance, on account of the use to which it has been converted by the manufacturing chemists for procuring a yellow pigment; and since the experiments of M. Lessaigne, it has been applied to the purpose of dyeing silk, cotton, linen, and woollen fabrics. It had been previously imported from America, but the expense of bringing it over was considerable. Shetland now rivals Baltimore in supplying Great Britain with this important acquisition to the arts.

To the earlier commerce of Shetland, the town of Lerwick seems to have owed its rise. It was first built about the beginning of the 17th century, when Bressay Sound was annually visited by not less than 2000 busses. For the sake, therefore, of an easy traffic with these ships in stockings and fresh provisions, houses close to the shore were erected; and hence the great irregularity which results from ranging the buildings agreeably to the indentations of the coast. The town has since gradually increased, and it now presents a lively appearance owing to the number of shops with which it is filled, and the sailors of all nations, who are engaged in making small purchases, while their vessels are moored in the harbour. Lerwick is, indeed, the seat of the commerce of Shetland, being also much indebted for its support to the vessels which touch at Bressay Sound in their voyage to the northern seas, and on their return home: among these are chiefly Greenlanders. In consequence also of the small barters that are made with foreign vessels, Danish and other coins pass more freely in the country than British money.

IX. Population.

The number of inhabitants was estimated in the year 1755 at 15,210; in the year 1793 at 20,186; in 1810 at 23,000; and in 1821 at 26,145.

X. Popular Manners and Customs.

Before we conclude this article, we shall attempt to give a sketch of the popular manners and customs of Shetland.

Physiognomy.—The men are rarely very tall, but remarkably well proportioned, light and nimble. In relinquishing, however, most species of domestic drudgery for the adventurous occupation of fishery, they have caused a more than ordinary portion of labour, fatal to the preservation of a delicate and symmetrical form, to devolve upon the poor females. The features of the Shetlanders are rather small, and have nothing of the harshness that so peculiarly distinguishes many of the Anglo-Saxon provincials in the north of England, or in some of the lowland districts of Scotland. The constitutional temperament of the Scandinavians is generally conceived to be sanguine, and since its characteristics are supposed to consist in a florid complexion, a smooth skin, and hair brown, white, or slightly auburn, the natives of Shetland give satisfactory tokens of their national descent. The elder Linnæus's description of the northern Europeans well applies to them: "Gothi corpore proceriore, capillis albidis rectis oculorum iridibus cinereo-cœrulescentibus."

Language.—When Orkney and Shetland were transferred from the government of Norway to that of Scotland, the Scandinavian natives of these islands gradually abandoned the Norse language: but they still retain many Norwegian terms, and, along with these, their own national accent, which is distinguished by an acuteness of tone and an elevation of voice, that has much of the spirit of the English mode of utterance, while their pronunciation partakes of the still more modulated and impasssioned tones of the Irish. But among none of the natives is to be found the Scotch peculiarity of expression, which is less diversified by alternations of grave and acute accents, owing to the effect of emphasis being conveyed in a prolonged utterance.

Dress.—The peculiar leathern dress used by the Shetlanders in their fishery at the Haaf has been described. Their common attire differs little from that of the inhabitants of the sea-coast of Scotland. To men whose chief occupation is fishing, the common sailor's jacket is a favourite garb. The red cap, which is a distinctive badge of the master of a family, merits particular attention. It is made of worsted, somewhat resembling in form a common double nightcap, but much larger, and gradually tapering to a point, while it hangs down the back after the fashion of the head-dress of a German hussar. It is also dyed with numerous colours. Frequently the men wear on their feet *rivlins*, which are a sort of sandals made of untanned seal-skin, being worn with the hair-side outwards, and laced on the foot with strings or thongs of leather. Their lightness is particularly adapted for treading with velocity over the soft heaths or scatholds of the country. The dress of the women merits little attention, since it does not differ materially from the fashion of the Scotch peasantry. The woollens which are worn are generally imported from Lancashire or Yorkshire, while some are manufactured in the country.

Moral Traits.—The natives of Shetland, considered as parishioners, are in general discreet and orderly. The influence of the minister has certainly been much strengthened by kirk-sessions, and the heavy penalties of the ancient country acts denounced against such offences as violations of the Sabbath, or the refusals of a householder to afford his family instruction in religion and morality: but it has been also increased by the services that he renders to his flock on all occasions of sickness. The reverence with which he is consequently held among the people, of whom he is a real guardian, has rendered the occasional public censures which he bestows, a punishment of the most dreaded kind.

A few of the unfavourable traits in the character of the Shetlanders have already come under notice. When a vessel is wrecked, they differ little from Cornishmen or Welshmen in their efforts to plunder. Of a similar character are their gross impositions practised upon strangers in their charges for boat fare. Indeed it is impossible to bind the Shetlander down to any specific agreement: whatever sum he may contract for as a fare, he endeavours during the whole of the passage to increase, which adds to the annoyance that is otherwise experienced; he is also in the habits of considering the extortion to which he makes the stranger submit, as of the same nature as the right that he assumes to plunder a wreck, and enumerates under the blasphemous title of "*God-sends*," a wreck, a drove of whales, and a boat-fare. Yet, after all, these revolting features of character are not peculiar to Shetland; they are to be found in too many districts of Scotland and England, which arrogate to themselves the character of being better informed.

But if the pillage of wrecked vessels be reconciled to a Shetlander's conscience as a *god-send*, or the pilfering of sheep out of a scathold be excepted from the prohibition contained in the eighth article of the Decalogue, it would be an injustice to his character not to state, that against other temptations to dishonesty, he is proof to a remarkable degree. "About two miles from Onzie Frith," remarks Dr. Hibbert, "the contents of my trunks, owing to the loss of my keys, were indiscriminately exposed, in a small house to more than a score of eyes, for several days together, but I was perfectly easy with regard to the safety of my property; nor was I in this or any other instance of the like kind, deceived in the confidence I had placed in the cottagers of Shetland."

Another amiable moral trait of this country is its great hospitality: this has been celebrated in the Northern Sagas, and there still remains all the practice of it that is recommended in the Havamaal of Odin. "To the guest who enters your dwelling with frozen knees, give the warmth of your fire: and he who hath travelled over the mountains hath need of food and well-dried garments." It is the best proof of the estimation in which this virtue is generally held, that the alleged absence of it in a very small district, named Coningsburgh, should render the inhabitants of it liable to unmeasurable reproach. In this province, the traveller, who, in the close of the evening, might have been compelled to supplicate for a night's lodging, met with a chilling reception, and was awakened at the first dawn of the day by a harsh-sounding warning to depart, expressed in the ancient Shetland language: "*Myrkin i livra: lurein i liunga; timin i guestin i geunga.*"—It is dark in the chimney, but it is light along the heath; it is now time for the stranger to be gone. "It thus became a custom," said Mr. Low of Orkney, who has recorded this expression, "when any one wanted to dismiss a stranger from his house if he staid too long, to recite in Norse the Coningsburgher's phrase." Again, in travelling through Shetland, there is the greatest scarcity of inns, and he who proceeds with a true spirit of independence, will find no great difficulty in inducing the cottagers to accept of an adequate remuneration for receiving him beneath their roof: but he must submit to great inconvenience, chiefly owing to the want of cleanliness in the Shetland hovels. This want of comfort, however, he will at any time prefer rather than be reduced to the necessity of seeking for gratuitous comfort in more commodious habitations; yet too frequently is the reluctance subdued, by the generous invitation which has met on his lonesome way the weary stranger.

Marriages.—Marriages take place in Shetland with little concern for the future. This was attempted to be corrected so early as the year 1680, by a law that might have been dictated by Malthus himself. Every person who had not forty pounds of free gear, or some lawful trade, was forbidden to marry: and none were allowed, under the penalty of ten pounds Scots, to set them house or land. It was formerly the custom for a young married couple to beg from each of their neighbours a supply of domestic articles, as a set-up for housekeeping; but this plan was obviated, by rendering it liable to the rigour of a law that punished with the stocks and juggs all tiggers (or beggars) of wool, corn, fish, &c. whoever they might be, and that inflicted the penalty of ten pounds Scots to any one who might grant them service or hospitality.

Patronymics.—Not many years since, it was very easy to know all the native inhabitants of Shetland, who distinguished themselves from Scottish settlers, by retaining in their names the use of patronymics. Thus, if the father's name was Magnus, the son's name (Laurence) would be Laurence Magnuson; and in the old records of the country it appears that the names of daughters were subjected to the same rule; there were, for instance, in ancient deeds, such appellations as *Madda Scuddadaughter* and *Freia Erasmusdaughter*.

Food.—It has been remarked that the food of the natives is chiefly Sillocks, or the small fry of the cole-fish, with which every voe swarms, and which seldom fail at any time to fill the *buidy* or fishing-basket with a meal. The result, however, of the ling fishery affords the means of purchasing flour from Scotland, to compensate for the deficiency of crops, which autumnal storms may destroy in a single night. The sources whence the Shetlander derives his support is, indeed, no where so happily illustrated as in the toasts that he gives in the hours of conviviality, the most popular of which is, "Death to da head that wears nae hair;" or, in less enigmatical words, *Death to the fish*. It was usual about sixty years ago, when a party was assembled at Johnsmas to drink success to the ling-fishery, for the principal person of the feast to address his comrades after the following manner: "Men and brethren, lat wis raise a helt. Here's first to da Glory o' God an da guid o' wir ain puir sauls, wir wordy land-maister, an wir lovin meat-mither, helt ta man, death to fish, and guid growth i' da grund." About Lammas, when from the length of the nights, and the rapidity of the tides, lines were often lost, the convivial sentiment was, "Helt ta man, death ta fish, and detriment ta nae man." But when the natives were about to quit the ling fishery, and to return home to the harvest, the hope expressed in the cottager's cups was, "God open da mouth of da gray fish, an haud his haund about da corn."—The last toast may require explanation. The *gray fish* are the fry of the coal-fish (Piltocks and Sillocks,) so named in contradistinction to ling, cod, tusk, hallibut, haddock, &c. which are called white fish. The ejaculation that God may *haud his hand about da corn*, implies the wish that the hand of the deity may preserve the grain from destructive tempests.

Among the dainties of a Shetland table, the tusk fish must be always considered pre-eminent: it is the most delicious of the Gadus species, and Thule no less deserves a pilgrimage to it from the epicure on account of this dish, than Plymouth, for the sake of eating John Dories. Another favourite Shetland dainty is known by the name of *Cropping moggies*, consisting of the liver of the cod mixed with flour and spice, and boiled in the fish's stomach: this preparation, when met with at the houses of the more opulent inhabitants, is excellent:—in the plainer form of *livered moggies*, the flour and spice being absent, it regales the fishermen at their summer lodges. The ancient Scandinavian beverage of bland, prepared from the serum of milk, is met with at almost every house. There is a great variety of shell-fish to be found in Shetland, that might add to the varieties of the table, particularly lobsters, which occur in abundance near Papa Stour, but none of these are very favourite kinds of food. In former times every dwelling had adjoining to it a skeo, which is a small square house formed of stones without any mortar, with holes through which the air may have a free passage; for which purpose the building was erected on a small eminence, being at the same time protected from the rain by a roof. Cod and ling were then caught near the shore, and the best of them being intended for sale, under the name of *stock-fish*, were hung up unsalted on poles, within a drying house of this kind, that the wind, in issuing through its crevices, might cure them: but as these fish could not always be preserved from putrefaction, they were at first, perhaps from necessity, consumed by families, until a relish for tainted food would naturally result from their constant introduction at meals. It is probably then from this cause, that though skeos are now in ruins, fish in a semi-putrescent state, named *sour fish*, or *souked fish*, are at the present day as agreeable to the Shetlanders as the tainted flavour of venison is to an English stomach. It was also customary before using beef or mutton, not to salt it, but to hang it up in one of these skeos, or in some cave within which the tide flowed, named a *helyer* or *hiallar*. But all the skeos are now roofless and in decay.

Habitations.—An account has already been given of the construction of the Shetland dwellings: they are built of rude stones, with a cement of clay, or they are still more coarsely formed of stones and clods. In most of the Shetland cottages the fire place is in the middle of the room. Windows are become much more general than they were some years ago; for, among some of the oldest habitations, no other light is received than through the aperture which allows an egress to the smoke. To this opening is given the Scottish name of *lumb*, but in the obsolete language of Shetland, it was called the *livra*,—a word resembling the ancient *liuren* or light-hole of the Norwegians. Yet many old Shetland houses are not destitute of that notable improvement of domestic architecture known by the name of chimney, an invention ascribed in northern annals to king Olaf Kyrre who lived in the eleventh century.

The byre or cow-house generally adjoins the dwelling, and is frequently entered by a common door, that introduces the stranger first to the cattle, and afterwards to the apartment devoted to the use of the family. In most of the Shetland habitations a partition of turf runs across the room, which is occasionally carried up to the height of the house, being intended as well for the purpose of storing up victuals as for a separate dormitory. But generally the beds, which consist of a few coarse blankets or straw, are placed in any convenient angle of the cottage. One or two cumbrous wooden chairs, designed for the heads of the family, with the addition of a few benches, constitute the heavy part of the furniture. Such is a specimen of the ancient cottage of Shetland: but in the south of the Mainland better dwellings of this kind are occasionally found. A melancholy want of cleanliness is too general a characteristic of the hovels of Thule.—The habitation of a farmer holding some little rank, has been described by Dr. Hibbert after the following manner. "His house was situated on the south side of the hill of Aithsness, upon the brow of the acclivity. A steep brown hill rose to the north, washed at its base by a transparent pool. The farm-house was built of the rough unhewn stones of the country; much green outfield, well cultivated, appearing in various patches along the valley. Stone-dikes ran round the dwelling in a zig-zag direction, enclosing it like so many outworks of a fortification. On a small adjoining eminence were the remains of a skeo, where was once prepared the blown fish and vivda that furnished a delicious repast for the ancient udaller. Before the door were placed a few stepping stones, somewhat difficult to trace, and intended to prevent a plunge, knee-deep, into the immense bed of compost that lay reeking all around. The visiter, after entering a dark and gloomy byre, which forms a part of the tenement,—after grazing the heels of the cows on the left of him, and feeling carefully along the surface of a partition to his right, may detect the latch of a door that leads to a spacious apartment containing a fire-place in the middle of it,—where the floor is of clay,—where the walls are thickly coated over with soot,—where are two long forms, on which the servants of each sex are seated, the mistress of the house being distinguished by a high and separate chair,—where, in one corner, is a favourite calf quietly regaling itself with a bowl of milk,—and where are two or three surly had-dogs stretched on the hearth, perfectly happy in the society of a miraculous quantity of cocks, hens and chickens, a sow and a playful litter of young ones. A rude partition divides from the main room a small private apartment, including within the recesses of its walls two or three press beds. The state dormitory, however, reserved for the opgester, is reached by scaling a wooden ladder, on each side of which are stored barrels of meal or oats, dusty tows, fishing-nets, sillock-rods, and various kinds of hand-lines; the middle of the room being reserved for a curtainless bed. There may the inmate, after commending himself to the guardianship of all good spirits, consign himself to repose, and rise in the morning cheered by the unobstructed rays of the sun, that light the room from an open fissure in the roof."

But, according to the same writer, the ancient Udaller, or small landed proprietor, lives in rather greater state. "When visiting the voe of Burrafiord," he adds, "I was, by the extreme lateness of the evening, under the necessity of availing myself of the custom of the country, where a stranger is perplexed for a lodging, which was to seek for hospitality in the nearest convenient house on my way. My boatmen led me to a small creek at the head of Burrafiord, where the setting sun brightened into a fine purple, a wild intermixture of crag and lake. The smoke arose from a low house, built of unhewn stones, after the most ancient fashion of the country; it was the *Head Buil* or manor-house of a small landed possessor of Aithsting, named the Laird of Fogrigate. On opening the door, I passed through a double range of servants of both sexes, who occupied forms disposed along each side of the room, and made suitable obeisance to the *hoy sædet*, or high seat of the house, filled by the laird himself, with all the patriarchal dignity, worthy that primitive state of manners described in an ancient poem of the 8th century.

Ipse insedit Ad utrumque latus,
Medio scamno; familia domus.

"Native Shetland ale was introduced, which was the first I had tasted in the country. It was not many days old, and had such a pleasant briskness in it, that it might have been seasoned with the tops of heather, after the recipe, as learned antiquaries would tell us of Pictish ale. But there was no other ingredient in it except malt; it was, as an Englishman in Harry the Eighth's time would have said, "As good as the King's ale, for it contained neither hops nor brimstone." The room to which I was shown for repose, served the double purpose of being a dormitory for the opgester (or guest,) and a granary for the family. A quantity of straw was strewed on the floor, and upon this was laid a sufficient number of *Kiverins* and blankets, with clean white sheets. The morning was announced by the grinding of the quern. Breakfast was got ready: my trunks furnished me with tea and sugar, and to a thrifty female I was indebted for cakes.

"Protulit tum Edda
Conspectum cinere panem,
Ponderosum et crassum
Plenum furfuribus."

It is almost needless to add, that the Shetland gentlemen of rank possess residences that may vie with many in Scotland. The house of Mr. Mouat of Bressay is a structure of much elegance.

Festivities.—The delight of the ancient Udaller's convivial hours, was in the recitation of Norwegian ballads. Shetland was from time immemorial celebrated for its native poets. Ronald, Earl of Orkney, being in the year 1151, shipwrecked near Gulberswick, was visited by two poets, Oddi Glumson the Little, and Armodr. The earl, who composed verses himself with great fluency and elegance, found them so well skilled in the same art, that he received them among the number of his retainers, and took them with him on his travels to the Holy Land. On the occasion of a public feast, he gave to Armodr, as an acknowledgment for his poetic talents, a golden spear. Not longer ago than seventy years, a number of popular historic ballads existed in Shetland; the last person who could recite them being William Henry, a farmer of Guttorm, in the island of Foula. Some kinds of poetry, as the historical ballads and romances which this old man could recite, were never sung but on a winter's evening at the fire-side. Others, under the name of Visecks, formed the accompaniment to dances, that would amuse a festal party during a long winter's evening. When the corn-waters of Hamburgh had gone merrily round, the tables labouring at the same time under the weight of skeo-dried vivda, sillocks, gammon, and reeked trout,—when the *gue*, an ancient two-stringed violin of the country, was aiding the conviviality of Yule, then would a number of the happy sons and daughters of Hialtland, take each other by the hand, and while one of them sung a Norn Viseck, they would perform a circular dance, their steps continually changing with the tune. In the middle of the last century, the Norwegian language remained in the country; and these visecks being soon lost, they were followed by playing at cards all night, by drinking Hamburgh waters, and by Scotch dances. The reel, upon being introduced, became highly popular; and a few original melodies adapted to it, were composed by native musicians of Shetland, the most popular of which was the Foula reel. To this tune, a song was afterwards adapted, named the Shaalds of

Foula, allusive to a profitable fishery that was long conducted upon these *shaalds*, or shoals, for cod; the words of which sufficiently express the freedom with which the Shetlander spent, in the conviviality of a winter, the hard-earned savings of a summer in the perilous fishery of the Haaf. When the ancient Udaller gave an entertainment, it was open to the whole country; but the strangers from the south, with more rigid notions of economy, corrected the generous custom, by rendering such feasts liable to the officious interference of the Ranselman, who was empowered to levy a fine upon any one who came to feasts uninvited. Marriages also, which were chiefly contracted during the winter, served to draw together a large party. It was, on these occasions, usual for the bridegroom to have his feet formally washed in water by his men; and in wealthy houses wine was used for the purpose. A ring was thrown into the tub,—a scramble for it ensued, the finder being the person who was to be first married. On the night before the marriage, the bride and bridegroom were not allowed to sleep under the same roof; and on the wedding-night, the bridegroom's men endeavour to steal the bride from her maidens, and a similar design on the bridegroom was made by the bride's maids. Last of all took place the throwing of the stocking, and "many other pretty sorceries." These customs are now gradually subsiding.

One sport, however, still retained on occasions of festivity, deserves particular notice. Olaus Magnus, in his account of the manners of the northmen, describes an ancient military dance as being common to them, which seems to have been achieved by six persons. It was accompanied by a pipe and song, the music being at first slow, and gradually increasing in celerity. The dancers held their swords, which were sheathed, in an erect position,—they then danced a triple round,—released their blades from the scabbards,—held them erect,—repeated the triple round, —grasped the hilts and points of each others swords, and extending them, moved gently round,—changed their order, and threw themselves into the figure of a hexagon, named a *rose*. They again, by drawing back and raising their swords, destroyed the figure which they had made, in order that over the head of each other a four-square rose might be formed. Lastly, they forcibly rattled together the sides of their swords, and by a retrograde movement ended their sport. The sword-dance performed by the Curetes of Papa Stour is not unlike the one now described; but since the residence of Scottish settlers in this country, it has sustained some modification, by being made the sequel to a sort of drama performed by seven men, in the characters of the seven champions of Christendom. This interesting masque is still performed by the inhabitants of Papa Stour in Shetland, but in a very few years it will cease to exist; on which account, we cannot help feeling some regret that the Highland Society, who, in their annual exhibitions, are laudably anxious to keep alive the ancient amusements of the north, should have never once thought of showing, that one of the oldest dances of Europe, truly worthy a warlike people, does not merely exist in the pages of the Waverley Novels, but can find a real illustration. The sword-dance has been minutely described by Dr. Hibbert.

After the sword-dance has been performed, it is not unusual to hear of the announcement of the guisards. A number of men enter the room dressed in a fantastic manner, their inner clothes being concealed by a white shirt as a surtout, which is confined at the waistband by a short petticoat, formed of loose straw, that reaches to the knee. The whole are under the control of a director, named a Scudler, which is an ancient name given to the pilot of a scuda, or twelve-oared boat. The scudler is distinguished from his comrades by a very high straw cap, the top of which is ornamented with ribbons. He is the proper *arbiter elegantiarum* of his party, regulating their movements, and the order in which they should alternately dance with the females assembled. The amusement thus afforded is the same that may be found in any politer masquerade, since it depends upon the guisards being able to conceal from the company who they are. The custom of paying visits to parties under the disguise of a mask, is described in Olaus Magnus's History of the Northern Nations.

Superstitions.—No country in the British dominions contains so many superstitions as Shetland, to which peculiar interest has been imparted since the publication of "the Pirate." Orkney and Shetland were for many centuries only semi-christianized; we therefore read, even in their present superstitions, the Pagan tenets which they originally entertained. In Orkney it was customary, even in the last century, for lovers to meet within the large circle of stones that had been in the earliest times dedicated to the king of the gods: through a large hole in one of the pillars the hands of contracting parties were joined, and the faith they plighted was named the promise of Odin, to violate which was infamous. Other mythological personages have in Shetland a considerable influence over the minds of the people even at the present day. The diminutive race of supernatural beings who inhabit the interior are described by the natives of Feroe as *Foddenskemand*, or underground men; in the Icelandic Edda they appear under the name of Duergar or Dwarfs. The Shetlander still *sains* or blesses himself as he passes near their haunts. They are described at the present day as a people of small stature, gaudily dressed in habiliments of green. They partake of the nature of men and spirits, yet have material bodies, with the means, however, of making themselves invisible, and they multiply their species.

Of mermen and merwomen many strange stories are told. Beneath the depths of the ocean, an atmosphere exists adapted to the respiring organs of certain intelligences, resembling in form the human race, possessed of surpassing beauty, of limited supernatural powers, and liable to the incident of death. They dwell in a submarine portion of the globe's surface, over which the sea, like the cloudy canopy of our atmosphere, loftily rolls, and they possess habitations constructed of the pearls and coralline productions of the ocean. Having lungs not adapted to a watery medium, but to the nature of atmospheric air, it would be impossible for them to pass through the volume of waters that intervenes between the submarine and supra-marine world, if it were not for the extraordinary power that they inherit, of entering the skin of some animal capable of existing in the sea, which they are enabled to occupy by a sort of demoniacal possession. One shape that they put on is that of an animal, human above the waist, yet terminating below in the tail and fins of a fish. But the most favourite form is the large seal or Haaf fish; for, in possessing an amphibious nature, they are enabled not only to exist in the ocean, but to land on some rock, where they frequently lighten themselves of their sea dress, resume their proper shape, and with much curiosity examine the nature of the upper world belonging to the human race. Unfortunately, however, each merman or merwoman possesses but one skin, enabling the individual to ascend the seas, and if, on visiting the abode of man, the garb should be lost, the helpless being must unavoidably become an inhabitant of our earth. Thus the Ve Skerries on the west of Shetland are, according to popular belief, the particular retreat of the green sons and daughters of the sea, where they are defended by a raging surf, that continually beats around them, from the obtrusive gaze and interference of mortals; here they release themselves from the skins within which they are enthralled, and, assuming the most exquisite human forms that were ever opposed to earthly eyes, inhale the upper atmosphere destined for the human race, and, by the moon's bright beams, enjoy their midnight revels.—The Shoopiltee is another mythological personage. He is the demoniacal Neptune of the north, who in Shetland assumes the form of a beautiful shelty, inviting some one to mount him, when he immediately rushes into the sea: at other times he assumes something of a human shape, though inclining to the nature of a horse, and is decked with fuci and various products of the seas; again, in the decided form of a shelty, he makes his haunts near water-mills, but when observed hastily withdraws himself into the burn, or vanishes in a flash of fire. This deity is the same to whom the Edda recommends the offering of a prayer for success in navigation, hunting, or fishing, since he gives to his votaries treasures, and even kingdoms. In Unst, it was customary to visit the head of a stream, named Yelaburn, or the Burn of Health, and to throw, as an acknowledgment to the water god, three stones on an adjoining site of ground. The pool of Helga Water appears to have been originally visited with the same intent. The natives were wont to walk round it in the course of the sun, observing strict silence in their perambulations, taking up water in their hands, and casting it on their heads.—Another spirit was named Brownie. In most northern countries, there was scarcely a family that in former times had not a domestic spirit. The Samogitæ, a people formerly inhabiting the shores of the Baltic, who remained idolatrous so late as the 15th century, had a deity named *Putscet*, whom they invoked to live with them, by placing in the barn every night a table covered with bread, butter, cheese, and ale. If these were taken away, good fortune was to be expected: but if they were left, nothing but bad luck. A similar tall "lubbar-fiend," in Shetland was inhabited in a brown garb of wadmel, and was accustomed by his influence to ensure a good grinding of corn, a good brewing of ale, a good separation of butter during churning, and protection for corn stacks against the greatest storm that could blow. In return, therefore, for these benignant offices, it was usual to apply to brownie's use a sacrificial stone, within which was a small cavity for the reception of a little wort, upon the occasion of every brewing; or when milk was churned, it was necessary that a part should be sprinkled with the same intent, in every corner of the house.

Magic was originally sanctioned in Scandinavia by Odin, and, during the Pagan state of Orkney and Shetland, was practised by individuals of the highest rank. The mother of Thorfin, Earl of Orkney, who lived in the 11th century, gave to her son a standard, embroidered with the signal of a raven, telling him, that if the fates had intended he should have lived for ever, she would have nursed him much longer in his cradle; but that life was finished more honourably with glory, than lengthened out with dishonour;—that although the standard on which she had expended all her magic art portended victory to him before it was carried, yet it might bring death to the bearer. The females, who, in Scandinavia or its colonies, had most distinguished themselves in the art of divination, were deified after their decease under the name of Nornies or destinies; and it was supposed, that upon the completion of their apotheosis, they had the power of controlling human events. In Shetland, the magic which existed so late as the last century derived its origin from the mythology of the Edda. It was the boast of the ancient Scandinavian sorcerer that he could understand the language of birds. Odin had always in attendance two ravens, who would fly the world over, and at dinner time return for the purpose of whispering in his ears all the occurrences they had either heard or seen. In like manner a witch of Shetland, who lived about the middle of the seventeenth century, was seen going to and from Brecon to Hillswick, accompanied by two familiars "in the likeness of two corbies that hopped on each side of her all the way." This appearance was deemed contrary to the nature of "wild fowls," and formed one of the charges against the unhappy woman, for which she was condemned to be worried at a stake. Another spell by which the magician of Shetland obtained a power over nature's operations was by means of knots, the superstitious regard for them seeming to have arisen from the use to which they were, from the remotest period, applied as memorials of events, or as inviolable pledges of agreement. Brand relates, that a Shetland witch on seeing a fowl which a sea-eagle was carrying through the air, took a string, and casting some knots upon it, the bird of prey let its intended victim fall into the sea. The application of a woollen thread, by way of charm, round a sprained limb, and the use of a certain number of mysterious knots, is a superstition still familiar to most of the northern countries of Europe. It was also usual with the Shetland magicians, like those of Scandinavia, to use incantations. "I know a song," said Odin, "of such virtue, that were I caught in a storm, I can hush the winds, and render the air perfectly calm." But the warlocks and witches of Thule used, by the same means, to raise tempests. About fifty years ago, a woman of the parish of Dunrossness, known to have a deadly enmity against a boat's crew that had set off for the Haaf, took a wooden basin, named a *cap*, and let it float on the surface of a tub of water; then, to avoid exciting suspicion, she went on with her usual domestic labours, and, as if to lighten the burthen of them, sang an old Norse ditty. After a verse or two had been recited, she sent a child to the tub, and bade him tell her if the cap was *whummilled*, or turned upside down. Intelligence was brought to her, that the water was moved, but that the bowl was afloat. She then continued her incantation, and once more broke it off, by requesting the child to again go to the tub, and tell her what he saw. The little messenger returned with the news that there was a strange swell in the water, and that the bowl was sadly tossed about. The witch then sang still more loudly, and, for the third time, sent the child on the same errand, who soon hastened back with the information that the water was frightfully troubled, and that the cap was whummilled. The enchantress, with an air of malignant satisfaction, then ceased her song, and said, "The turn is done." On the same day, news came that a fishing yaul had been lost in the roust, and that the whole of the crew had been drowned.—Again, the witch of Shetland had, like Odin, the great father of Scandinavian magic, the power of undergoing a transmutation of shape resembling that of various animals. Marion Pardon of Hillswick, conceived a malice against the crew of a fishing boat, and transforming herself into the likeness of a piltock-whale, under this form upset their vessel. She was convicted of the crime by the confession of another witch, and by the well-known test of the *bahr-recht*, or law of the bier. Being commanded, along with Swene, her husband, to lay their hands on two of the dead bodies that were found, one of them bled at the *craig-bane*, and another in the head and fingers, "gushing out bluid thereat, to the great admiration of the beholders, and revelation of the judgment of the Almightie." On this irrefragable proof of murder, admitted, as the indictment expressed, not only in this country but likewise in most foreign kingdoms, the unfortunate woman was executed.

In short, the light of Christianity was feebly opposed to the phantoms of the Scandinavian mythology. When popery commenced its influence over the minds of the people, a belief in the existence of gods, giants, or dwarfs, still remained, with this qualification only, that they were fallen angels of various ranks belonging to the kingdom of darkness, who, in their degraded state, had been compelled to take up their abode in mountains, springs, or seas. These were tenets conveniently subservient to the office of exorcism, which constituted a lucrative part of the emoluments of the inferior Catholic clergy, with whom Orkney and Shetland were in ancient times overrun.

Demons were thus kept in order by a kind of spiritual police, which prevented them, owing to the interference of exorcism, spells, or charms, from breaking into human habitations, or trespassing on the lands of the udallers, to the injury of live stock and the fruits of the earth. But Brownie was tolerated even by the most zealous Catholic. He was an inmate in every house, assisting in the operations of threshing, churning, grinding malt or mustard, and sweeping the house at midnight: a standing fee being required for him each night of white-bread, and milk or cream, spread upon a table. There was also another reason for not offering him any disturbance. According to Olaus Magnus, the northern nations regarded domestic spirits of this kind as the souls of men who had given themselves up during life to illicit pleasures and transgressions, and were doomed, as a punishment, to wander in the shape of spirits for a certain time about the earth, and to be bound to mortals in a kind of servitude. It would have been, therefore, an opposition to the decree of heaven, to refuse the penal labours of such slaves, and a sorry description of policy to turn away an useful servant, although an unearthly one, who could be kept at the cheapest of rates.

The early Christian preachers seeing the influence which the mythology of the Edda had over the minds of the people, gave to all the pagan gods, giants, or dwarfs, the name of *trols*, a term indicative of the seductive or alluring influence which they possessed over the souls of mankind. The word still preserves its general import, as the trol or *trow* of Shetland designates either a fairy of the hills, a merman or merwoman, or the shoopiltee of lakes and burns. It was also supposed, that witches and warlocks, by a compact with Satan himself, were enabled to command the assistance of the demons of the pagans, who, having been driven from heaven, had taken shelter in caverns, seas, and lakes, or had become the drudging domestic spirits of particular families: and when the magic of Odin was modified by the introduction of Christianity, it was imagined that many diseases were induced by a sort of demoniacal possession that took place in different parts of the body, and that a cure was to be effected by obliging a demon to enter the body of some other animal. It was also a belief, that if any person was emaciated with sickness, his heart was wearing away, which was attributed to the agency of a demon, who took for that purpose, the form of a worm; and that if a new habitation could be procured for the evil spirit, a cure would take place. A Shetlander then sought out a charmer, who, after melting some lead, and using mysterious forms, allowed it to drop through an open sieve into cold water, and if an image, bearing some faint resemblance to the heart, was, after repeated trials, produced, it was worn by the patient as an amulet, to entice the demon to quit the vital organ which he was tormenting. If, by no ingenuity, the figure of a heart could be effected, the chance of recovery was proportionally diminished. This superstition, under a few modifications, still prevails.—But eventually, the true warlocks were the priests, who by means of crosses, benedictions, amulets, prayers, and other godly gear, could at any time produce supernatural effects, that in days of paganism depended on incantations, knots, or runic characters: and when reformation was introduced in the land, and the rites and ceremonies of popery condemned as idolatrous, it was still found not very easy to shake the popular faith in the efficiency of many of the ancient ceremonies of the Roman Church used to insure good success in fishery and a good harvest. The charmer of Shetland would mutter some religious words over water, in imitation of the practice of the Catholic priest, and the element was named *fore-spoken water*: boats were then sprinkled with it, and pains in the limbs, by being washed with it, were *healed*. If a beast was wounded with elf shot by the trows, the charmer would find out the hole, inscrutable to common eyes, in which the arrow entered, and would wash the place with forespoken water. By the application of this fluid were the effects counteracted of an evil eye, or of an evil tongue.

The last modification which took place of witchcraft, arose from a doctrine taught by the reformers, that the light of the gospel could penetrate by its effulgence into the very domiciles of unclean spirits, and expel them to unknown regions. When a view like this gained ground, it will scarcely create surprise that the Bible should become no less useful an instrument in the hands of charmers than crosses, forespoken water, and benedictions. It was recommended, that the lonely wanderer by night among the bleak scatholds of Thule, should bear in his hands the holy scriptures, as a means of screening himself from the attacks of the trows or demons of the hills. But the magic of Thule was in no way so successfully combated as by the terror of the law. The rapacity of Earls Patrick and Robert Stewart caused them to make a diligent search after all witches, in order to obtain possession of their estates, which became due to them by forfeiture; nor was their example unfollowed, for thirty or forty years afterwards, by those who succeeded them in the government of the country. Even so late as the commencement of the last century, the Shetland witches were, as Brand says, talked of so much anent their devilry, that he was told it was dangerous going to or living in that country.

But the ancient superstitions of Shetland are gradually passing away, a belief in the trows of the hills, or in mermen and merwomen being limited to remote districts, where there is less intercourse with the world. A few warlocks or witches still exist, who have the power of taking away the profits from corn or cattle. A fear is entertained of an evil eye, and a person has been known to fall ill upon being cursed by an enemy. Parents have a dread of their children being praised or complimented on being fat, thinking that children so lauded are doomed to die; this notion is a very old one, having been ascribed by Gellius to a people of Africa. Charmers also exist, who find stolen goods, and by means of knots, cure diseases. But all these illusions must eventually yield to the force of education.

Diseases.—In so variable a climate as that of Shetland, phthisis pulmonalis, pneumonia, croup, and scrofula are, as we might expect, very frequent. There is a great variety of cutaneous complaints, tinea capitis being the most common. The very interesting disease of sibbens, important in the history of syphilis with which it has been confounded, often prevails in Shetland. Owing to some peculiarity of food, conjoined with the nature of the climate, dyspepsia and liver complaints are very common. Occasionally fever rages in the cottages; and from their close construction, by which air is excluded, the contagion proves highly fatal. Every member of a family has been known to be attacked with typhus; and as the dread created among neighbours is very great, the situation of a family left without succour to linger, or perish, is too painful to contemplate. Cases of this sort have too often occurred. Nor is the assistance of a medical man always to be obtained; for when patients do not live on the mainland, but in detached islands, ferries must be crossed, upon which no boat in winter, with the least chance of safety, can venture. In some parts of Shetland, divine worship is interrupted by fits resembling hysteria, which spread from one female to another; but as these paroxysms are easily counteracted by inducing such opposite states of mind, as arise from a sense of shame, they are under the control of any sensible preacher, who will expose the folly of yielding to a sympathy so easily resisted, or of inviting such attacks by affectation. The small pox has at intervals been very fatal in Shetland; and it is to be lamented that vaccine inoculation is far from being universal.

Longevity.—Cases of great longevity in Shetland have, at various times, been recorded, particularly in the statistical accounts published, and in Buchanan's history. How far they are to be depended upon, it is difficult to say. Ages appear from 90 to 105, and even 120. A native of Walls, of the name of Laurence, is said, at the age of 100 to have married a wife, and when 140 years old to have gone out to sea in his little boat. But Brand, the honest missionary, heard of a case far more wonderful;—a man of the name of Tairville, who lived 180 years, and during all this time never drank beer or ale. He was descended from a family remarkable for their longevity, his father having attained even a greater age than him self.

Native Medicines.—In Shetland there are several popular medicines. Scurvy grass is used in cutaneous complaints, butter-milk in dropsy, shells of whelks calcined and powdered in dyspepsia, and a variety of steatite, named in the country kleber, in excoriations. A man now dead in Northmavine, was a successful inoculator with variolous matter, which he was accustomed, with the view of depriving of its virulence, to dry in peat-smoke; he then covered it with camphor, buried it in the earth, and before applying it, retained it in this situation for so long a period as seven or eight years. But the mode of letting blood, known from time immemorial, deserves the most particular notice. It has been described by Dr. Copland in a Medical Thesis. When the native chirurgeon is called in, he first bathes the part from which the detraction is to be made with warm water, and then draws forth his cupping machine, which consists of nothing more than the upper part of a ram's horn perforated at the top, and bound round with a soft piece of cotton or woollen rag. In applying it to the skin he sucks out a little of the included air, takes off the horn, makes upon the surface of the part that has been gently raised, six or seven slight incisions, again fixes the cupping instrument, freely draws out the air by the reapplication of his lips to it, and either by insinuating his tongue within the perforation, or by twisting round it a piece of leather or bladder, prevents the ingress of fresh air. He next uses coarse cloths, wrung out with warm water, to stimulate the flowing of the blood, and when the horn is half filled it leaves the skin and falls off. The same process is repeated several times, until a sufficient depletion has been made. It is worthy of remark, that the African negroes described by Park have a similar mode of cupping; but it would be passing an undeserved affront to the natives of Thule to add, that, on the theory of a philosopher, who maintains that the manners of an uncultivated people are in all periods and countries the same, such a coincidence ought to have been expected.

We have at length concluded our view of the history and present state of the Shetland islands, which form a neglected and (strange to add!) an unrepresented province of the British dominions; but we may hope that a better acquaintance with the natural advantages which they possess in their fisheries, mines, and other sources of natural emoluments, may recommend this country to the attention of a liberal and enlightened legislature, and that it may be advanced to a state of political importance which it has not yet had the good fortune to experience.

SHETLAND, New South, an extensive tract of uninhabited land, situated to the south of Cape Horn. It is said to have been first discovered by Gherritz, a Dutch navigator, in 1599, but some doubt exists with regard to this fact. It was rediscovered in 1819, by Mr. Smith, the commander of an English merchant vessel, in a voyage from Monte Video to Valparaiso. The circumstance which gave rise to the name of New South Shetland being applied to these islands, was their lying in nearly the same degree of south as the Shetland islands are in north latitude. Its appearance is that of a succession of islands, stretching in a northwest direction.

The ingredients of the rock of which the Shetland islands are formed, appear to be quartz, with disseminated iron pyrites, and quartz in prismatic concretions, copper green, and copper pyrites. Among the minerals, is a rose coloured apophyllite, which has not the tesselated structure so common to this substance. The islands, which are almost all intersected with icebergs, and some of them covered with snow, present a rocky and barren appearance, and, with the exception of a few patches of short grass and some moss, are almost totally devoid of vegetation. These islands also exhibit volcanic appearances, as smoke had been observed issuing from the clefts in the rock of one of them. In consequence of the scarcity of herbage, it is impossible that any terrestrial animal could exist. But there are several species of amphibious animals, the principal of which are the sea elephant and the fur seal. The first of these acquired its name from the male having a cartilaginous substance, about five or six inches long, extending from the nose, similar to the trunk of the elephant. The birds are not numerous. They consist of a small species of penguin, fresh water ducks, Port Egmont hens, white pigeons, aglets, snow birds, and grey and blue peterels. See Weddell's *Voyage towards the South Pole*, 2d edition, p. 129.

SHIELD, see Armour.

SHIELDS, North, a market and sea-port town of England, in the county of Northumberland, is situated on the northern bank of the Tyne, about one and a quarter mile from its entrance into the German Ocean. The oldest part of the town is a long narrow street on the side of the river, but the town now contains several excellent streets, two handsome squares, and a market place unusually spacious. The most fashionable part of the town is Dockuray Square, which is neatly built, and is inhabited by wealthy shipowners. On one side there is a commodious quay, at which ships of 300 tons may unload, and another side is decorated with a fine stone edifice, now used as an inn. The parish church was built in 1659. It is situated on the north side of the river, and is a plain but commodious edifice; a steeple was erected upon it some years ago, and musical bells placed in it. There is in the town a commodious Scotch church, an elegant Catholic chapel near the north entrance to the town, and a meeting house for Independents. There is here also a theatre, a new market place, a good subscription library, a dispensary, a large Lancasterian schoolhouse, a lying-in hospital, an asylum for sick and friendless women, several charity schools, and many thriving benefit societies.

The principal manufacturing establishments in this town are yards for ship and boatbuilding, a rope and sailcloth manufactory, a cast iron foundry, a tobacco manufactory, a tannery, a skinnery, a manufactory of glass and fur. The harbour can accommodate 2000 vessels, and during spring tides, ships of 200 tons can pass the bar. The principal trade of this port consists in exporting coals, though a few vessels were employed in the American and Baltic trade. The want of a custom-house is severely felt here, as all vessels are obliged to clear out from Newcastle, a distance of nine miles up the river.

The following was the population in 1821:

Inhabited houses - - -	853
Families - - - -	2081
Ditto employed in trade - -	762
Ditto in agriculture - - -	1
Males - - - -	3815
Females - - - -	4360
Total population - - -	8205

There are at the foot of the town two lighthouses, which are kept up by the Trinity House of Newcastle. Near the lighthouses stands Clifford's Fort, built in 1672, which completely commands all vessels that enter the river. See the *Beauties of England and Wales*, vol. xii. part i. p. 89.

SHIELDS, South, a market town of England, in the county of Durham, is situated near the mouth of the Tyne, almost opposite to North Shields. Most of the streets of this town, with the exception of those on the Bank top, and in the market place, are narrow and the houses indifferently built; and its appearance is greatly disfigured by a number of artificial hills, stretching to the east and south sides, and formed by the accumulated cinders of the salt-works, the refuse of the glass houses, and the ballast and gravel thrown out by the light colliers. Some of these hills have been built up, and have a very singular appearance when seen from the south. The church of St. Kilda, which is a chapel of ease to Jarrow, was, with the exception of its plain and square tower, rebuilt in 1811 at an expense of £5000. Though rather heavy externally, it is neat and commodious within. On the chain above the chandelier is a very elegant model of the life boat. It stands on the south side of the market place, which is a spacious square, having in its centre the town house, with a colonnade beneath it, erected at the expense of the dean and chapter of Durham. There are here several dissenting meeting houses, the chief of which is that belonging to the Methodists, finished in 1809 at an expense of £3800, and capable of holding 1700 persons. There is likewise in this town a new theatre, several public schools and thirty benefit societies. Subscription assembly rooms are opened every winter. The whole town, with the exception of three houses and a meeting-house, is held by lease under the dean and chapter of Durham.

The principal establishments for manufactures of South Shields are yards for shipbuilding, glass works for flint and crown glass, soap works, salt works, salammoniac works, extensive roperies and breweries. Salt was formerly manufactured here to a very great extent. About sixty years ago, no fewer than 200 large pans were fully occupied. There are however only four or five pans at present employed. The ground formerly occupied by the salt works has been converted into docks and yards for building and repairing ships. There are no fewer than *eleven* of them which are capable of holding sixteen vessels. The number of ships belonging to this town is about 500. Among the machines for taking ballast from ships, is one erected by Messrs. Newmarch and Company, which carries it through a tunnel several hundred yards long. The life boat was invented here, as already described in our article Boat. The town of South Shields is built almost exactly on the site of the Roman station *ad Tinam*, which occupied the eminence on the south point of the harbour.

The following was the population in 1821:

Inhabited houses	724
Families	2286
Ditto employed in trade	2243
Ditto in agriculture	2
Males	3638
Females	5247
Total population	8885

See the *Beauties of England and Wales*, vol. v. p. 153.

SHIPBUILDING.

INTRODUCTORY OBSERVATIONS.

In no period of the world has the subject of naval architecture had higher claims on public attention than the present, and to our own country in particular, it is an art of such transcendent importance, that no means ought to be left untried to give to it every perfection of which it is susceptible. Nor is it only in a commercial point of view that shipbuilding is valuable to man, since by the enterprise that fortunately characterises the modern navigator, the ocean is become one of the high roads of civilization,—perhaps the highest; and therefore in the successful cultivation of the various arts connected with navigation and commerce, every lover of human improvement must feel an interest proportionate to the influence which they are now universally allowed to exercise on the improving destiny of man.

There are three capital points of view in which naval architecture may be contemplated. *First*, as regards the means it affords for the purposes of war; *secondly*, as it relates to commercial enterprise and speculation; and *thirdly*, as it is connected with human improvement, the enlargement of geographical knowledge, and the extension of the blessings of civilization. The cultivation of the first is unfortunately rendered necessary by the peculiar condition of the world; and perhaps the second and third are in some degree protected and assisted by it; but it is the successful advancement of the latter, that renders the study of naval architecture most pleasing, and elevates it to a rank with those arts which essentially minister to the happiness and well being of man. Commerce indeed is productive of unnumbered blessings. Its theatre is the world; and the wide spreading waters of the ocean form the links of social harmony and love. The most distant nations are by its means connected;—national jealousies and prejudices become softened;—the wandering savage learns to value the blessings of social life; and the various productions which the wisdom and beneficence of the Supreme has rendered peculiar to particular climates and countries, are, by the arts connected with shipbuilding, distributed through every part of the globe, to which the wide spreading enterprise of man has penetrated.

Little more than a century and a quarter have elapsed since the theory of mechanics was first applied to the construction and management of vessels, in a work published at Lyons in 1696 by Paul Hoste,* and entitled, "*Theorie de la Construction des Vaisseaux.*" Prior to the publication of this interesting treatise, experience and imperfect observation were the guides of the shipbuilder. The torch of geometry had not then illuminated his path: nor were the maxims of mechanical science applied to his daily labours. Ships were constructed by rules, which a long succession of centuries had esteemed as infallible, and no man ventured to question their accuracy and origin. After a long night of darkness, however, arose Bernouilli, Bouguer, and Euler, who joined to the highest theoretical attainments, clear and definite conceptions of the practical applications of analysis to some of its most important elements. In the hands of Euler in particular, the subject first assumed a regular and systematic form; yet from the peculiar difficulties connected with the inquiry, much, very much remains to be done, to give to its theoretical investigations those capabilities of application which the inquiry so particularly demands. Since the time of Euler, it has been enriched by the labours of Clairbois, of Chapman, of Atwood, and of some others; and the labours of the two latter have done much for its advancement. Its precepts and rules, however, are still too much influenced by caprice, by prejudice, and chance. The rigid and scrutinizing spirit of geometry calls for a more precise application of its rules;—and where, we would ask, can its severe and unalterable precepts meet with a more extended field of application?

At the present moment indeed, a spirit of inquiry seems to be awakened respecting shipbuilding, which no antecedent period ever exhibited. The public attention has in a peculiar degree been drawn towards it, partly, perhaps, from apprehensions respecting the possible rivalry of other states; partly from the successful applications of mechanical science to its various branches, by the genius and intelligence of Sir Robert Seppings; and partly from the establishment of the school of naval architecture in Portsmouth dock yard, and from the admirable union of theory and practice which characterises the course of instruction employed in that most useful institution.

It is the judicious and proper union of theory and practice that is wanted to carry this very important art onwards to perfection. "Practical knowledge alone would be insufficient, nor would the highest theoretical skill be all that would be required. The two must be united,—cordially and harmoniously united. Practice must not decline the assistance of theory, nor must theory disdain to be taught by the lessons of practice."† "There are many principles," says Mr. Atwood, "deducible from the laws of mechanics, which it is probable *no species of experiment, or series*

* Pere Pardies, and the Chevalier Renaud, published some partial observations on the theory of naval architecture prior to 1696, but the treatise of Paul Hoste was the first work in which the subject was considered in a systematic manner.

† Harvey on Naval Architecture, Annals of Philosophy, vol. viii. p. 445, new series.

of observations, however long continued, would discover; and there are others no less important, which have been practically determined with sufficient exactness, the investigation of which it is scarcely possible to infer from *the laws of motion*; the complicated and ill-defined nature of the conditions, in particular instances, rendering analytical operations founded on them liable to uncertainty." It is true indeed, as the same writer remarks in another place, that "although all results deduced by strict geometrical inference from the laws of motion, are found, by actual experience, to be perfectly consistent with matter of fact when subjected to the most decisive trials, yet in the application of these laws to the subject in question, difficulties often occur, either from the obscure nature of the conditions, or the intricate analytical operations arising from them, which either renders it impracticable to obtain a solution, or, if a result is obtained, it is expressed in terms so involved and complicated, as to become in a manner useless as to any practical purpose. These imperfections in the theory of vessels are amongst the causes which have contributed to retard the progress of naval architecture, by increasing the hazard of failure in attempting to supply its defects by experiment; for when no satisfactory estimate can be formed from theory, of the effects likely to ensue from adopting any alteration of construction that may be proposed, doubts must unnecessarily arise respecting its success or failure, which can be resolved only by having recourse to actual trial; a species of experiment rarely undertaken under the impressions of uncertain success, when the objects are so costly, and otherwise of so much importance. To the imperfections of theory may also be attributed that steady adherence to practical methods, rendered familiar by usage, which creates a disposition to reject, rather than to encourage proposals of innovation in the construction of vessels: the defects or inconveniencies which are known, and have become easily tolerable by use, or may perhaps be the less distinctly perceived for want of comparison with more perfect works of art, being deemed preferable to the adoption of projected improvements, attended by the danger of introducing evils, the nature and extent of which cannot be fully known. These are amongst the difficulties and disadvantages which have concurred in rendering the progress of improvement in the art of constructing vessels extremely slow, and left many imperfections in this practical branch of science which still remain to be remedied."*

Another important consideration which has tended to retard the progress of naval architecture, is the immense variety of vessels, which the peculiar circumstances of climate, varieties in the extent and depth of waters and of seas, have rendered necessary to man; each variety differing in proportion and form, in their methods of rigging, and in their modes of navigation; some being adapted for limited voyages in narrow and contracted channels, others for voyages the most extended in the widest oceans; some for winds of almost a permanent character, and others for all those uncertain varieties of weather, which mark so many of the regions of the earth.

Amidst this almost infinite diversity, we may however trace, in numerous instances, indications of something like general laws. In those vessels, for example, which are destined for extended voyages, we find their extreme breadths to be between a third and fourth of their lengths. In vessels of a smaller size, the breadth bears a greater proportion to the length, than in ships of a higher class. The elevation of the deck above the surface of the water has likewise limits, which are regulated by the peculiar destination of the vessel. All ships, moreover, have their maximum of breadth, a little before the middle; the forms of their forward and after parts are variable, but still distinguished in all cases by this peculiar feature, that the figure of the latter part is more slender, or as it is technically expressed, is leaner than the former. In ships destined to bear heavy burdens, the bottom is fuller to admit of greater capacity for stowage, in opposition to those which are built for speed and velocity, which have uniformly their lower parts of a sharper figure. The line of the keel also does not run in a plane parallel to the fluid surface, but has a greater draught of water in the after-part of the vessel, than in the forward; that both the stem and the stern have a rake or inclination between certain limits: that in the rigging of ships, some have one mast, others two, and most three masts, adapted in their diameters and altitudes, to their peculiar circumstances; that the centres of gravity of all vessels are found a little before the middle of their lengths, and that the centre of gravity of the sails is uniformly met with before the centre of gravity of the ship.

Thus it appears, that amidst the seeming diversity characterising the numerous branches of this very important subject, there are indications of general laws to be found, which experience, in a long succession of ages, has taught the navigator to follow, in order to succeed in his adventurous enterprises. And it is remarkable in how many instances the results of uneducated men have anticipated the soundest deductions of the most enlarged theories; and how unconsciously they have employed, even in their pastimes and sports, those very principles on which the philosopher raises the noblest monuments of his fame. "The savage who never heard of the accelerating force of gravity, yet knows," says Mr. Stewart, "how to add to the momentum of his missile weapons, by gaining an eminence; though a stranger to Newton's third law of motion, he applies it to its practical use, when he sets his canoe afloat, by pushing with a pole against the shore; in the use of his sling, he illustrates with equal success, the doctrine of centrifugal forces, as he exemplifies (without any knowledge of the experiments of Robins) the principle of the rifle barrel, in feathering his arrow." And just so is it in the steps which have marked the progressive advancement of naval architecture. The practical knowledge which the framer of the canoe exercises, "is obtruded on the organs of external sense by the hand of nature herself." He found, for example, that a particular disposition of the sail of his little bark would give to it a greater velocity than any other. A change of position of his own body, or of a stone in the bottom of the canoe, would alike influence its sailing qualities. These to him would be maxims of great practical value; would be treasured up and recollected, applied on every necessary occasion; in time communicated to his fellow-navigators, and at last identified with the general habits of his tribe. From such be-

*Philosophical Transactions for 1798, pages 203, 204.

ginnings it is, that naval architecture has arisen; and the philosophical observer endeavours to draw from the maxims which have guided even uneducated men in a long course of ages, those general laws, which, when moulded into a systematic form, enable him to perceive relations still more extended and general.

It is remarkable however, that although experience seems to have taught mankind, that certain general relations in the formation of ships, are necessary to be observed, in order to insure success in their construction; yet within the limits which this experience has revealed, so many varieties of form have been produced, as to create in the qualities of the vessels constructed the greatest diversity. Some ships, when constructed with only a tolerable approximation towards the limits which experience seems to have approved, appear to possess every good property we can desire; whereas others, framed apparently with equal care, and with no visible deviation from the limits before observed, will nevertheless, from differences in the mode of stowage, and from different methods of management when at sea, display qualities altogether at variance with the former. It often happens also, that constructers, in order to avoid one defect, create another, and sometimes, too, when endeavouring to get rid of a bad quality, the evils arising from it are augmented; and so intricate are the conditions connected with any theoretical investigation of the cause, that any attempt to account for it in such a way, has but slender chances of success. The great object indeed in the construction of a vessel, is to secure to it as many good qualities as possible; that if it be necessary in one case to sacrifice any portion of an acknowledged good property, in order to secure a more advantageous application or extension of another, care must be taken, that no greater proportion of the first should be abandoned, than the actual necessities of the second require; in other words, that the aggregate of *both* should approximate as nearly to a maximum as possible.

We have seen, however, that experience has taught us certain principles in shipbuilding, which may be safely adopted as data, on which to ground systems of reasoning connected with the properties to which those principles refer: and is it not therefore possible, by careful attention, to discover *other* properties, at present classed with the accidents and chances attendant on fortunate constructions; but which would, nevertheless, in the hands of one competent to the undertaking, be found to possess some definite relations to other general laws? All ships, it has been before remarked, have their centres of gravity a little before the middle of their lengths. This is known in a general way; but the precise quantity of the deviation of this very important point, from the centre of the length, cannot, in the present imperfect state of our knowledge, be made known. Would no useful results therefore flow from an experimental inquiry into the exact position of this centre? Or rather, might we not say, would not many conclusions of the first importance to naval architecture, be obtained from a digest of the properties of a few of the best ships of each class of the British navy? Mr. Major, at present foreman of Chatham dockyard, and formerly of the school of naval architecture, published, in the Annals of Philosophy for November 1824, a paper on this very important subject; setting forth the advantages that would accrue to shipbuilding, by obtaining, experimentally, many of its leading elements, such as the foreign and light displacements of our ships of war; their principal dimensions, such as the greater axis of the load water plane, the breadth and draught of water; the forms and areas of the load water, and midship sections; the place of the centre of gravity of the entire ship—*not from hypothesis, but experiment;* the position of the centre of gravity of the displacement; the elevation of the metacentre, at the mean height of the ports out of the water; the dimensions of the masts and sails, with the position of the centre of effort of each sail, the force of stability at some determined angle, &c. &c. These elements, it must be admitted, are of the highest importance to naval architecture; and from their correct and accurate determination, would result much useful knowledge. Mr. Harvey, in the number of the same Journal, for January 1826, has a paper on the same subject, and in which he particularly insists on the advantages likely to result from a practical exemplification of Mr. Major's plan. Mr. Harvey proposes to have all *the elements that may be deemed necessary to be determined* as well as *the essential steps on which they depend*, methodically arranged in tables, according to the relation which the different forms bear to each other. "I know of nothing," observes Mr. Harvey, "that at the present moment would so much tend to increase our stock of information on shipbuilding as Mr. Major's proposal: since it would be carrying at once into the very heart of shipbuilding, that spirit of genuine induction, which in so many other branches of knowledge, has produced such mighty consequences."—"Let us inquire," says Mr H., "how we obtain information in other cases; how the philosopher works in his difficult investigations, and what are the instruments and methods employed by him when tracing the hidden mysteries of nature? Are they not *Experiment,—Observation,*—a careful watching after resemblances and relations of every kind? Does he not analyze every principle, separate every part, and in the end collect into general and connected laws, the individual results which his sagacity has discovered?" "Just so," continues Mr. H., "ought it to be in the pursuit of naval architecture; for there are about that subject, elements of a very peculiar kind, whose individual properties and collective laws, it is of the highest importance to determine. Much may indeed be said about theory; *but pure theory has yet done little for shipbuilding; what we want is a theory founded on the basis of experiment and observation.* The first mathematician in Europe may speculate for ever on the forms of floating bodies; he may dazzle his imagination with his ideal creations; he may multiply his analytical combinations, and pile his highest orders of integrals on each other; and yet, when called upon to make his practical applications, his formulæ almost lose their identity, and all his golden speculations vanish. But place in the hands of such a man a well-digested body of experimental results; show him how, in numerous instances, one property of a vessel has been invariably found connected with another; give to him those *constants* which are to link together the disjointed elements of his problem; furnish him with *experimental data* on which he can depend, and from which he can with confidence draw such results as his growing investigations require; and we shall find in the end a striking contrast to his former results. The data supplied to him will have disclosed relations never before anticipated, and conclusions never before imagined. Naval architecture would thus be in a high degree benefited; and an art which, it is not too much to say, is of the very *first importance for the British nation to cultivate and encourage*, would be freed from the trammels of uncertain and antiquated rules, and placed on a basis better suited to its dignity and value."

But, it may be asked, to what causes are we to attribute so singular a neglect of an art, so essential to the welfare of Great Britain, as the art of shipbuilding confessedly is; and how is it that states, confessedly our inferiors in maritime importance and strength, should excel us in the construction of their ships? To this it may be replied, that our triumphant superiority on the ocean affords a ready solution. Our superiority has induced neglect, while other nations, jealous of our nautical power, have strained every nerve to rival and surpass us, and *have endeavoured to make up the want of numbers by superior constructions.* The French, for example, have endeavoured, and in many cases have succeeded, in producing better sailers; and the Americans, by enlarging the scale of their different ships of war, are endeavouring to turn the balance against us. France, to obtain all superiority, wisely enlisted on her side the genius and science of her geometers. By prizes, by public rewards, by honourable distinctions, by every thing that could excite emulation and scientific enterprise, she invited her geometricians to consider all the great problems connected with shipbuilding; and to transfuse into the practical operations of her dock-yards, all that the most enlightened theories could teach. Some advantage surely must result to an art to which such a mind as D'Alembert's could direct its attention. It is impossible for a mind, accustomed to the higher orders of human thought, to descend to the lower walks of human contemplation, without the latter being in some degree improved. A mere theorist, applying his speculations to the practical details of an art, can do nothing; but a man, whose habits and modes of thought are built upon the genuine principles of inductive science,—who looks at shipbuilding, for example, neither with the eye of a merely speculative curiosity, nor with the blank intelligence that too often unfortunately characterises the daily operators in the mechanical arts, can scarcely direct his attention to any one of its departments, without in some degree imparting to it a benefit.

Shipbuilding, to Britain, may with perfect justice be styled a National Art. It is one even more necessary to our national existence than those miracles of mechanical skill which have placed our arts and manufactures on so proud and elevated a level. Destroy our naval superiority, and our lofty pre-eminence in commerce will soon be humbled in the dust. The navy is the sinews of our strength—the arm that gives us all our political importance, and makes the name of Britain known, respected, and feared in the remotest regions of the globe. And what, we would ask, is the proud term Navy, which as Britons we so often quote with exultation and hope, but a name identified in the closest and strongest way with the art which it is the object of this paper to illustrate? Give to our navy, therefore, we would say, *not only numbers, but every advantage which science and intelligence can bestow.* Let naval architecture be regarded peculiarly as a *national art.* Let its first elements, its feeblest beginnings, as well as its highest attainments, be fostered and encouraged. Let public honours and national rewards be bestowed on those who add to its perfection. Let our men of science be induced, like Euler, Bouguer, and D'Alembert, to look to it as an object to which their high attainments may be applied, with the full and certain prospect of honour and renown.

Some steps towards this most desirable end may, however, be traced in the establishment of the College of Naval Architecture in Portsmouth Dock-yard, an institution which has already done much good, and which, if continued with energy and spirit, will do much more. Before the establishment of this college, the officers and leading men of our dock-yards were drawn from the working men of those establishments; and *they* were recruited by means of apprentices, destitute, in many cases, of the commonest rudiments of education. From such men, excepting perhaps a few highly gifted minds, what else could be expected but the same blind routine of practice that distinguished their forefathers? Accordingly, we find that the commissioners appointed in 1795 to revise the civil affairs of the navy, remarked, that the class of persons from whom the foremen, the master shipwrights, and the surveyors of the navy were chosen, "had no opportunity of acquiring even the common education given to men in their rank of life; and that they rise to the complete direction of the construction of ships, on which the safety of the empire depends, without any care or provision having been taken, on the part of the public, that they should have any instruction in mathematics, mechanics, or in the science or theory of naval architecture." The death-blow to this most lamentably imperfect system, was however given by the establishment of the college before alluded to; and we have only to hope that the success of the institution will be commensurate to the wishes of its most sanguine admirers. The candidates for admission are examined before the commissioners of the dock-yard, the professor of the Royal Naval College, and the lieutenant-governor. They are required to be intimately acquainted with the English language, so as to write it grammatically, and from dictation; they are to be able to read and translate the French language; they must be well grounded in the first six books of Euclid, together with the eleventh, and algebra as far as quadratic equations. At the period of examination also, a printed paper is placed before each candidate, containing a number of geometrical and algebraic problems, which he is required to work out on paper; and those are selected as the successful candidates who have displayed the greatest talent in the examination. During the seven years that they remain in the establishment, they resume the study of geometry with its applications; enter on a more enlarged course of algebra, pursue trigonometry, examine the theoretical and practical details of mechanics and hydrostatics, and close their inquiries on this interesting head, by an enlarged course on the differential and integral calculus. In the theory of naval architecture, they study the admirable papers of Atwood, contained in the *Philosophical Transactions*,* and also some of the best continental works on the subject. After obtaining sufficient elementary knowledge, they are employed in constructing original designs of ships of war, ascertaining their displacements, the centres of gravity of their displacements, and of the whole masses of the ships and their equipments, considered as heterogeneous bodies. To this is added, the most exact and accurate inquiries connected with the stability, both according to the metacentric method of Bouguer, and to the more perfect and precise investigation of Atwood. Comparisons also are instituted—the qualities of English ships are compared with those of a foreign built—their several properties are analyzed—the good qualities are combined so as to remedy the bad, and to produce in their ultimate application the most perfect design.

But it is not to theory only that their attention is directed. The practical details of the art receive a large proportion of their attention. They are effectually taught how to lay off ships in their practical construction, and in making the drawings which are necessary for the execution of the work in the progress of the building. The adz and the line are put into their hand like the humble operative at the dock side, and a vigilant practical shipwright examines into the minutest details of their duty. Engaged therefore in the morning, we will suppose, in studying the theory of their profession—in calculating the displacement—in investigating the properties of the midship section—estimating the power and influence of the sails—or endeavouring to catch a glimpse of the deep and recondite laws that regulate the resistance of fluids—they turn in the afternoon to the practical details of their art—in shaping and adjusting timbers —filling up the component parts of Seppings' diagonal framing—bolting together the timbers of his circular sterns, and observing in those numerous cases which the eye of theoretic intelligence is in general so ready to catch, the actual application of rules which occupied their morning thoughts. What else, we would ask, is necessary to make a complete and perfect shipwright? He has the amplest and best theories known continually before him, and the most enlarged practice, to exemplify their application. During this course of rigorous and unrelaxing labour, both of body and mind, annual examinations are held before the commissioner of the dock-yard, the admiral of the port, the lieutenant-governor of the college, and the first lord of the Admiralty. These examinations, both in mathematics and the theory and practice of shipbuilding, are very severe, and considerable study and preparation are required to pass them with credit. After finishing their course of studies at the college, they are removed to the different dock-yards, to fill the situation of subordinate officers; from which situations it is the professed intention of Government to promote them to those of the higher offices, and eventually to that of surveyor of the navy.

But the studies of the members of this college are, however, but begun, when the term which marks their apprenticeship has expired. Naval architecture is a jealous mistress, and requires the undivided man. Not the devotion of a few years, but of a life, consecrated to its pursuit. Year after year, with unwearied zeal, must be devoted to its interests; and the cordial and uninterrupted pursuit of its varied details, must meet with that reward which attends industrious labourers in other departments of the arts.

It has been objected, however, to this institution, that its establishment has a tendency to check those honest and praiseworthy exertions which many among the great mass of the operative shipwrights in the dock-yards were formerly stimulated to make, by the hope of filling those situations which are to be now occupied by the members of the college. But to this it may be replied, that the Admiralty and Navy Board, with a wise and proper forethought, have by no means closed the avenues of promotion to this useful and deserving class of men. Very recently, indeed, we have seen an example of an operative promoted to the rank of a foreman, and a draughtsman of the old institution of things promoted to a similar situation. And this is just as it should be. Among the many operatives which a dock-yard presents, there must be some few at least deserving of a better fate, than to spend the long term of their lives in a perpetual state of unceasing labour—some, too, though working at first as humble shipwrights, yet deserving from their talents to rise to command. The great object in a well-regulated community, is to encourage ability wherever it appears; and we are persuaded that the welfare of the country will be essentially promoted by fostering native talent wherever it appears.

The objections, however, that are sometimes raised against the College of Naval Architecture, that science is unnecessary to a shipbuilder, and that time is misspent in cultivating mechanics, hydrostatics, and fluxions, are too ridiculous to merit a serious refutation in this place; and they are only alluded to, that the future historian of naval architecture, when tracing the effects and influence of the establishment of the college, may class it among the anomalies which distinguished its history. To suppose for a moment, that in a fabric so massy and stupendous as a ship, destined for all the terrible purposes of war, or to bring to us, from the most distant regions of the globe, cargoes of the most bulky and unmanageable kind;—which in its progress has to cross wide and immeasurable seas, agitated at times by the unbridled fury of the wind,—that no science is necessary in her construction, is to imagine an anomaly of the most monstrous kind. Science is the basis of every well-ordered machine. Science was the groundwork of all that Watt, Smeaton, or Wren ever achieved; and can science be unnecessary in the formation of a ship? Science indeed has hitherto been too much neglected in our dock-yards. We have trod long enough in the blind and uncertain steps of our forefathers; and the establishment of the College of Naval Architecture must be numbered among one of the most fortunate events of the age; and, though not found in the ranks of its members, we look to it with pride and satisfaction.

In concluding these introductory observations, we would remark, that naval architecture is in so peculiar a degree *a national art*, that we could wish to see a society formed for its particular cultivation. There are so many advantages to be derived from the co-operation of numbers in the prosecution of scientific pursuits—advantages first pointed out by the prophetic mind of Lord Bacon, and which the experience of the last two centuries has so abundantly confirmed, that it seems wonderful no attempt has been made to organize a society on a great and permanent scale for the improvement of shipbuilding. And Mr. Harvey has remarked, in the *Journal* of the Royal Institution, "that there is perhaps no subject which requires more essentially the aid and co-operation of numbers than naval architecture; involving as it does so extensive a field for inquiry, and so beset, as all its elements are, with difficulties of so peculiar and intricate a

* It is much to be desired that these admirable dissertations were reprinted in a separate form, and enriched by appropriate notes, for the use of our students in Naval Architecture.

kind. At the present moment also, there is a spirit of inquiry abroad respecting shipbuilding, which no antecedent period ever exhibited, and which, if taken at the flood, and before the causes that have awakened it subside, must produce consequences of a very important kind. What therefore seems to be wanting," continues Mr. Harvey, "is a sort of focus, or common point of union, to rally the disjointed and insulated speculations now afloat respecting it, and to concentrate the efforts of those who feel interested in its advancement. This might be most readily and effectually done, by instituting a society, the object of which should be, to encourage theoretical and experimental inquiries connected with naval architecture; and to publish from time to time in its transactions, such papers of approved merit as might be laid before it at its meetings."

The hint contained in this quotation is too important to be forgotten; and we earnestly hope to see it perfectly realized at no very distant time. We have seen, in the cases of the Astronomical and Geological Societies of London, how much their formation has contributed to quicken the cultivation of the interesting objects for which they were instituted; how by the one the astronomer has been stimulated to watch the celestial concave with greater earnestness and zeal; and how the other has tended to unfold, by gradual and successive steps, the nature and constitution of the crust of this lower world. Now why, we would ask, could not the same objects be attained for naval architecture? If the union of numbers has quickened geological, and added to the splendour of astronomical science, why should not an association of men, devoted to the theoretical and practical cultivation of shipbuilding, produce similar effects? The single subject of the resistance of fluids requires it alone; and when we see the magnitude of the obstacles that impede the march of the great national art we allude to, we earnestly hope that no endeavours will be wanting to surmount them.

It shall now be our object to enter into some of the theoretic and practical details of this important subject; and as we would on the one hand endeavour to avoid every thing which bears the aspect of *merely speculative inquiry, with no practical object in view*, so we would on the other avoid any description of those merely practical details of the art, which can only be acquired at the dock side, or which have been already minutely and clearly detailed by the practical writers on the subject. We shall therefore begin with the consideration of the displacement, an element which meets us on the very threshold of the inquiry.

OF THE DISPLACEMENT.

We refer to the article Hydrostatics for the consideration of the principle, that a body specifically lighter than water will sink in the fluid, until it has displaced a portion of it, equal in *weight* to the entire body itself. On this simple elementary law of Hydrostatics is primarily founded the process commonly employed by naval architects for determining the *displacement* of a vessel.

By the displacement of a ship we are to understand the cubical contents of that part of it which is below the water's surface, and which, it is obvious, must be more or less, according to the degree in which the ship is immersed, by the variable conditions of its lading.

In making a design for a ship, the first object of the constructer must be, to form as accurate an estimate as possible of its weight; and if this is to be done without any assistance derived from former constructions, exact calculations must be made of the dimensions and specific gravity of all the materials to be employed in her formation; the number of guns she is destined to carry; her complement of men; and the quantity of provisions and stores necessary for her complete equipment. When her total weight is thus determined, the constructer must endeavour to obtain for her a corresponding displacement, and at the same time secure to her such dimensions, as shall impart to her every property he may desire, and, if a ship of war, to ensure her lower deck guns a sufficient elevation above the water's surface. The displacement therefore is a fundamental element in shipbuilding, and on its right determination depends many important considerations.

If the form of the body immersed in the fluid were generated according to any known and determined law,—if, for example, it partook of the figure of any solid of revolution, the application of the particular rule of mensuration belonging to that figure, would readily furnish the solidity of the part immersed. But there is no certain form yet determined for a ship's bottom: and, accordingly, no approximate formula has yet been devised, which can furnish, by a short and convenient operation, the displacement. Bouguer it is true, attempted an approximation of the kind, by assimilating a ship's body to a spheroid; and then estimating the contents of its displacement at $\frac{11}{21}$ of the rectangular solid formed by the three principal dimensions of the ship—its length at the water's surface, and its breadth and depth estimated at and from the same plane. This method, however, although it might afford tolerably correct results for ships whose fulness of figure approached nearly to a spheroidal form, yet in vessels of a sharper class, the errors arising from its application would be too considerable to admit of its employment in any other way than as an approximation of the roughest kind.

Accordingly, constructers have had recourse to the well-known method of equidistant ordinates; a process contrived by mathematicians to obtain the areas and cubical contents of bodies, whose forms are destitute of symmetry and proportion. It consists essentially, in the case of a solid, in dividing it into an *unequal* number of laminæ or sections of uniform thickness, and determining their aggregate solidity by means of the formula

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3},$$

in which Σ denotes the sum of the *first* and *last* ordinates, S the sum of the *even* ordinates, s that of the *odd* ordinates, and i the *common interval* or distance between the ordinates: and we shall now proceed to exhibit its application, by calculating the displacement of a seventy-four gun ship. This may be enunciated as a

PROBLEM

To determine the displacement of a vessel, having her *Sheer plan* or *Elevation*, and *Body plan* or *Plan of Projection* given.

Solution.

The displacement of a vessel may be calculated by *horizontal* laminæ or sections, or by laminæ or sections estimated *perpendicularly*: or as is most desirable, by sections both horizontally and perpendicularly, and taking the mean of both, should the two results not exactly agree. This latter mode will be adopted in the succeeding investigation.

To accomplish it, let the sheer draught represented in Fig. 1. Plate CCCCLXXXVIII. be referred to, and in which W *w* denotes the intersections of the plane of the water's surface, with the plane of projection, or in other words, the water line of the ship, and at the common interval of one foot, let other planes be supposed to pass parallel to the plane of flotation, through the points 2°, 3°, 4° . . . . 20°, 21°, 22°, and 23°. This mode of operation will therefore divide the portion of the ship immersed into twenty-three uniform laminæ, the lowest of which is denoted by the dotted line X x. The same series of sections or water lines are also represented as passing transversely through the points 1°, 2°, 3° . . . . 21°, 22°, 23°, in the body plan denoted by Fig. 2; and the contour or bounding figure of each section is denoted by the curve lines which pass respectively through the points . . . . 10°, 13°, 16°, 19°, &c. in Fig. 3 of the same plate. The water line, or that which corresponds to W *w* in Fig. 1, is denoted by the external curve in Figure 3.

The different curves produced by these water sections, are, it will be perceived, of very variable forms, and their ordinates therefore must be of variable magnitudes. To ascertain these at uniform intervals, the ship is supposed in the next place, to be intersected

by transverse planes perpendicular to the water's surface, passing through the points 5', 4', . . . 1, 2, 3, ... 25, 26, 27 . . . . . . 4'', 5''; those between the points 1 and 27 being at the common interval of 6 feet from each other; those abaft the plane 1, at the equal interval of 3.4249 feet; and those before the plane 27, at the equal interval of 1.5 feet.

These sections, therefore, intersecting the body transversely, must disclose, from the variable form of the ship's hull, new curves for their respective boundaries. These are represented in the body plan, Fig. 2; the main section passing through ⊕ 15, in Figures 1 and 3, being denoted by the external curve in Figure 2. In like manner, the sections passing through the several points 5', 4', . . . 1, 2, 3 . . . 25, 26, 27 . . . 4'' 5'', in Figures 1 and 3, are represented by corresponding curves in Figure 2. Thus by the horizontal and vertical planes, which by the conditions of the investigation are made to intersect the body, two series of curves are produced, mutually intersecting each other. From these points of intersection are derived the various ordinates contained in the following table, and which we shall now proceed to describe.

FOR FINDING THE DISPLACEMENT.

1 and 27.				Common interval 6 feet.								Semi-horizontal areas between vertical sections 1 and 27.	Horizontal ordinates between vertical sections 1'' and 5''. Common interval 1 foot.	Ordinates of vertical sections between 1'' and 5''. Common interval 1.5 feet.					Semi-horizontal areas before section 5''.	Semi-horizontal areas before section 25.	Total areas of semi-horizontal sections.

This table, it will be perceived, is divided both horizontally and vertically. The *horizontal* sections, which in Figures 1 and 2, were supposed to pass through the points 1°, 2°, 3°,......21°, 22°, 23°, are designated by corresponding characters in the first *vertical* column. And in like manner, the first *horizontal* series of numbers,

5′, 4′ . . . . 1, 2, 3 . . . . 25, 26, 27 . . . . 4″, 5″

represents the *vertical* sections alluded to above.

To explain the method by which the ordinates are measured and recorded, let the horizontal section denoted by 16° in Fig. 3. be selected. This section, like every other section of the same kind, being from the nature of the transverse section, intersected by them, let the sections which pass through the points 6, 12, 18 and 24 be selected for the purpose of illustration, and let C, D, E and F, denote also the points in which they meet the contour of the horizontal section assumed. If then the ordinates C 6, D 12, E 18, and F 24, be severally measured by means of the scale attached to the drawing, they will furnish respectively the measurements recorded in the horizontal column denoted by 16°, and the vertical columns denoted by 6, 12, 18, and 24, and which measurements are respectively 10.25, 16.2, 16.1, and 7.25. In like manner let the horizontal section denoted by 10° be assumed; and let the vertical sections selected be those which pass through the point 2′, 5, 20, and 2″, and their intersections with the horizontal section in the points G, H, I, and K. If, therefore, the ordinates G 2′, H 5, I 20, and K 2″, be respectively represented on the scale of equal parts, the numbers 3.6, 16.6, 21.3, and 1.2, will be obtained, as recorded in the horizontal column 10° of the table, and vertical columns 2′, 5, 20, and 2″.

But the same measurements might have been obtained from the body plan, fig. 2. For let the horizontal plane denoted by 10°, be again referred to, and let the curves produced by the transverse sections 2′, 5, 20, and 2″, be those denoted by the same numbers on the body plan; and let the points of intersection be G, H, I, and K, as before. If the ordinates GO, HO, IO, and KO, be measured from the proper scale of equal parts, the values 3.6, 16.6, 21.3, and 1.2, will be obtained as before. And according to either of these methods, therefore, may the different ordinates be obtained, which are recorded in the several columns of the table.

In the next place, we shall proceed to show how the areas of the different sections may be obtained both horizontally and vertically, by means of the formula for equidistant ordinates before given; and how, in the next place, from the areas thus found, may be derived the solidities of the laminæ themselves.

Let it be required therefore, in the first place, to determine the area of the first horizontal section, or that denoted in the table by 1°. Then, since the formula $(\Sigma + 4\,S + 2\,s)\frac{i}{3}$, requires the sum of the *extreme ordinates*, four times the sum of the *even ordinates*, and twice the sum of the *odd ordinates*, let the ordinates for the sections between 1′ and 5′ be in the first place selected, as follows:

Extreme Ordinates.	Even Ordinates.	Odd Ordinate.
0.8	5.1	10.9
17.4	14.8	2
18.2 = Σ	19.9	21.8 = 2 s
	4	
	79.6 = 4 S	

and since $\frac{i}{3} = \frac{3.4249}{3} = 1.1416$, we shall have

$(\Sigma + S + 2\,s)\frac{i}{3} = (18.2 + 79.6 + 21.8) \times 1.1416$

$= 136.54$, which, it will be observed, is the area entered in the first line of the vertical column, entitled *semi-horizontal areas between vertical sections 5′ and 1′.*

In the next place, let the ordinates for the sections between 1 and 27 be selected.

Extreme Ordinates.	Even Ordinates.	Odd Ordinates.
17.4	20.1	21.7
11.0	22.5	22.95
	23.25	23.55
28.4 = Σ	23.75	23.95
	24.1	24.25
	24.4	24.5
	24.55	24.55
	24.55	24.55
	24.5	24.4
	24.3	24.25
	23.95	23.4
	22.15	20.15
	16.9	
		282.2
	299.0	2
	4	
		564.4 = 2 s
	1196.0 = 4 S	

and since in the present series of sections,

$\frac{i}{3} = \frac{6}{3} = 2$ feet, we shall have

$(\Sigma + 4\,S + 2\,s)\frac{i}{3} = (28.4 + 1196.0 + 564.4) \times 2$

$= 3577.6$, which is the first area entered in the vertical column, entitled *semi-horizontal areas between vertical sections* 1 and 27.

In the third place, let the ordinates for the sections 1″ and 5″ be selected.

Extreme Ordinates.	Even Ordinates.	Odd Ordinate.
11.0	9.0	6.6
0.75	3.9	2
11.75 = Σ	12.9	13.2 = 2 s
	4	
	51.6 = 4 S	

and since in this case $\frac{i}{3} = \frac{1.5}{3}$ we shall have

$(\Sigma + 4\,S + 2\,s)\frac{i}{3} = (11.75 + 51.6 + 13.2) \times 0.5 =$

38.27, which is the first area entered in the vertical column named *semi-horizontal areas before section* 27. To this being added the small area 3.15 for the fore part of the stem, produces 41.42 for the total semi-horizontal area before section 27.

By referring to Fig. 1. Plate CCCCLXXXVIII, we shall perceive that the three sets of ordinates investigated above, comprised only the portion of the vessel included between the points 5′ and 5″; and that beyond those points two supplementary areas are to be found, one embracing a horizontal section of the rudder, and the other a horizontal section of the stem. These areas are, by proper measurement, found to be each 3.15, and are entered in the first lines of the columns entitled *semi-horizontal areas abaft vertical section 5*, and *supplementary semi-areas.*

Thus it appears that the area of the first horizontal section is made up of five portions, and which may be arranged as follows:

Semi-horizontal area abaft vertical section 5′	= 3.15
Semi-horizontal area between vertical sections 5′ and 1′	= 136.54
Semi-horizontal area between vertical sections 1 and 27	= 3577.6
Semi-horizontal areas before section 27	= 41.42
Total area of semi-horizontal section 1°	= 3758.71

By a similar mode of proceeding must the areas of all the horizontal sections, from 1° to 21° inclusive, be obtained, the results of which are recorded in the last vertical column of the table.

Let the next example selected for illustrating the application of the formula of equidistant ordinates, be the determination of the main or midship section denoted by 15. In this case we shall obtain the following investigation:

Extreme Ordinates.	Even Ordinates.	Odd Ordinates.
24.55	24.65	24.75
0.75	24.7	24.7
	24.5	24.2
25.30 = Σ	23.8	23.2
	22.55	21.8
	21.0	20.0
	19.0	17.9
	16.7	15.1
	13.2	10.3
	3.6	1.35
	0.75	
		183.3
	194.45	2
	4	
		366.6 = 2 *s*
	777.80 = 4 S	

and since $\frac{i}{3} = \frac{1}{3}$ we shall have

$$(\Sigma + 4\,S + 2\,s)\ \frac{i}{3} = (25.3 + 777.8 + 366.6) \times \frac{1}{3}$$

= 389.9, which, it will be remarked, is the area entered in the column devoted to the vertical section ⚲15, at the third horizontal line from the bottom.

In addition to this, there is the small area .03 to be added, and which produces for the total area of the vertical section ⚲15, the quantity 389.93, and which also is entered in the lowest line of the table.

Precisely after this manner are the areas of all the other vertical sections estimated, and their results recorded in the last mentioned line of the table.

But it may be necessary to allude more particularly to the minute areas constituting the last horizontal line but one of the table. By reference to Fig. 1. Plate CCCCLXXXVIII, we shall perceive that from the circumstance of the keel not being parallel to the fluid surface, the horizontal plane corresponding to the lowest section 23° will leave *abaft* the vertical section 16, (at which point the keel and the horizontal plane passing through 23° are coincident,) a portion of the keel *below* it; but *before* that section, a portion of the keel *above* it. Hence the areas recorded in the horizontal column in question, are *positive* abaft the 16th section, and *negative* on the other side of it.

Let us, in the next place, proceed to apply the formula in question to the determination of the *solidities* of the *horizontal* and *vertical* laminæ into which the ship has been divided. For this purpose, we have for the *horizontal sections* the areas recorded in the last vertical column of the table; and for the *vertical sections* the several areas recorded in the three principal departments of the lowest horizontal line of the table.

TO DETERMINE THE SOLIDITY BY HORIZONTAL SECTIONS.

Extreme Ordinates.	Even Ordinates.	Odd Ordinates.
3758.71	3719.32	3667.62
183.41	3602.27	3523.40
	3453.70	3308.58
3942.12 = Σ	3176.43	3030.13
	2879.89	2723.79
	2554.86	2380.11
	2197.81	2012.72
	1811.33	1573.24
	1295.79	937.11
	417.83	
		23156.70
	25109.28	2
	4	
		46313.40 = 2 *s*
	100437.12 = 4 S	

and since $\frac{i}{3} = \frac{1}{3}$, we shall have

$$(\Sigma + 4\,S + 2\,s)\ \frac{i}{3} = (3942.12 + 100437.12 + 46313.4) \times \frac{1}{3} = 50230.88,$$

which is the value of the solidity by horizontal sections. If to this last quantity be added the solidity of the part below section 21°, and which has been estimated separately on the ground of greater accuracy and convenience, we shall have 50230.88 + 260.15 = 50491.03 *for the absolute semidisplacement by horizontal sections.*

To determine the same by VERTICAL SECTIONS, we must perform the following calculations; and, first, for the semi-solidity between the sections 1′ and 5″.

Extreme Ordinates.	Even Ordinates.	Odd Ordinate.
15.72	33.76	61.74
126.98	95.10	2
142.70 = Σ	128.86	123.48 = 2 *s*
	4	
	515.44 = 4 S	

and since $\frac{i}{3} = \frac{3.4249}{3} = 1.1416$, we shall have

$$(\Sigma + 4\,S + 2\,s)\ \frac{i}{3} = (142.7 + 515.44 + 123.48) \times 1.1416 = 892.3$$

for the semi-solidity required.

In the next place, to obtain the semi-solidity of the sections between 1 and 27, we have

T 2

Extreme Ordinates.	Even Ordinates.	Odd Ordinates.
126.98	178.41	221.52
69.15	256.17	285.38
———	311.15	332.51
196.13 = Σ	349.16	361.96
	370.87	378.45
	383.73	387.22
	389.97	389.93
	389.90	387.34
	383.41	377.08
	366.93	351.95
	330.35	301.79
	262.95	212.49
	145.75	———
	———	3987.62
	4118.75	2
	4	———
	———	7975.24 = 2 *s*
	16475.00 = 4 S	

and since $\frac{i}{3} = 2$, we shall have

$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (196.13 + 16475.00 + 7975.24)$ $\times\ 2 = 49292.74$, for the semi-solidity required.

In the third place, to obtain the semi-solidity for the sections between 1″ and 5″, we have

Extreme Ordinates.	Even Ordinates.	Odd Ordinates.
69.15	49.72	31.21
5.60	15.05	2
———	———	———
74.75 = Σ	64.77	62.42 = 2 *s*
	4	
	———	
	259.08 = 4 S	

and since $\frac{i}{3} = \frac{1.5}{3} = 0.5$, we have

$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (74.75 + 259.08 + 62.42) \times 0.5$ $= 198.12$ for the solidity of the sections desired.

Hence, by taking the semi-solidity of the part abaft the vertical section 5′, and also the semi-solidity of the part before section 5″, and which results are recorded in the lowest horizontal line of the table, we shall have by arranging the results:

Semisolidity abaft vertical section 5′	=	90.04
Semisolidity between sections 1′ and 5′	=	892.30
Semisolidity between sections 1 and 27	=	49292.74
Semisolidity between sections 1″ and 5″	=	198.12
Semisolidity before section 5″	=	13.70
Semi-displacements by vertical sections		50486.90

The *sum* of the semisolidities determined by the *horizontal* and *vertical* sections will give the total mean displacement. Thus,

Semisolidity by horizontal sections	=	50491.03
Semisolidity by vertical sections	=	50486.90
Mean displacement in cubic feet	=	100977.93

To bring this quantity into tons, it must be divided by 35, the number of cubic feet of sea water in a ton, and which produces for the displacement required 2885.084 tons.

We shall now pass to the consideration of the centre of gravity of displacement.

ON THE CENTRE OF GRAVITY OF DISPLACEMENT.

To determine the centre of gravity of displacement, it may, in the first place, be remarked, that from the symmetrical form of the body, when it is divided by a vertical longitudinal plane passing through the middle of the keel, it must be necessarily situated in this plane, and that our object, in the first place, therefore, must be to determine the distance of the same point *below* the plane of the water section; and, secondly, to find its position with regard to the length.

To determine its distance below the plane of the water section, we must again have recourse to the last vertical column of the general table, and multiply the numbers contained in it successively by 0, 1, 2, 3, 4, 5 . . . . . 18, 19, 20, as in the following table, in order to apply them to the formula of equidistant ordinates.

Areas of semihorizontal sections.	Multipliers.	Resulting products.	Areas of semihorizontal sections.	Multipliers.	Resulting products.
3758.71	0	0000.00	2554.86	11	28103.46
3719.32	1	3719.32	2380.11	12	28561.32
3667.62	2	7335.24	2197.81	13	28571.53
3602.27	3	10806.81	2012.72	14	28178.08
3523.40	4	14093.60	1811.33	15	27169.95
3453.70	5	17268.50	1573.24	16	25171.84
3308.58	6	19851.48	1295.79	17	22028.43
3176.43	7	22235.01	937.11	18	16867.98
3030.13	8	24241.04	417.88	19	7939.72
2879.89	9	25919.01	183.41	20	3668.20
2723.79	10	27237.90			

To apply the column entitled resulting products, to the formula for equidistant ordinates, we shall therefore, have

Extreme Products.	Even Products.	Odd Products.
0000.00	3719.32	7335.24
3668.20	10806.81	14093.60
———	17268.50	19851.48
3668.20 = Σ	22235.01	24241.04
	25919.01	27237.90
	28103.46	28561.32
	28571.53	28178.08
	27169.95	25171.84
	22028.43	16867.98
	7939.72	———
	———	191538.48
	193761.74	2
	4	———
	———	383076.96 = 2 *s*
	775046.96 = 4 S	

and since the common interval of the horizontal sections is one foot, we have $\frac{i}{3} = \frac{1}{3}$; and therefore

$(\Sigma + 4\ S + 2\ s)\ \frac{1}{3} = (3668.20 + 775046.96 +$ $383076.96) \times \frac{1}{3} = 387264.04$ is the moment of the displacement between the horizontal sections 1° and 21°. To this, however, must be added the moment of the part below section 21°, amounting to 5489.05, giving for the moment of the entire semi-displacement, the number 392753.09.

But by a well-known principle of mechanics, if the moment of the semi-displacement be divided by that semi-displacement, the result will be the required depth of the centre of gravity of displacement below the water section. This depth therefore is $\frac{392753.09}{50188.96}$ = 7.78 feet. The semi-displacement here employed is the mean of the displacement determined by the horizontal and vertical sections.

To determine, in the next place, the position of the centre of gravity of displacement with respect to the length of the vessel, we must have recourse to the lowest horizontal column of the general table before referred to, and refer all the calculations to the primitive vertical plane marked 1.

In the first place, the moment of the rudder will be found by multiplying the semi-solidity abaft the vertical section 5′, by the distance of its centre of gravity from the primitive plane 1, and which is

$$90.04 \times 16.4 = 1476.66 \quad . \; . \; . \quad (M)$$

Secondly, to find the moment of the part between the vertical sections 5′ and 1′, we have

Semivertical areas between sections 5′ & 1′	Multipliers.	Resulting products.
126.98	0.00	000.00
95.10	3.425	325.72
61.74	6.850	422.92
33.76	10.275	346.88
15.72	13.700	215.36

and applying the column of resulting products to the formula for equidistant ordinates, we shall have

Extreme Products.	Even Products	Odd Product.
000.00	325.72	422.92
215.36	346.88	2
215.36 = Σ	672.60	845.84 = 2 s
	4	
	2690.40 = 4 S	

and since $\frac{i}{3}$ = 1·1416, the formula will produce

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (215{\cdot}36 + 2690{\cdot}40 + 845{\cdot}84) \times 1{\cdot}1416 = 4282{\cdot}83 \; . \; . \; . \; . \; . \; . \; (M')$$

Thirdly, to find the moment of the portion of the vessel comprised between the vertical sections 1 and 27, we have the following table:

Semivertical areas between sects 1 & 27.	Multipliers	Resulting products.	Semivertical areas between sects 1 & 27.	Multipliers.	Resulting products.
126.98	0	0000.00	389.93	84	32754.12
178.41	6	1070.46	389.90	90	35091.00
221.52	12	2658.24	387.34	96	37184.64
256.17	18	4611.06	383.41	102	39107.82
285.38	24	6849.12	377.08	108	40724.64
311.15	30	9334.50	366.93	114	41830.02
332.51	36	11970.36	351.95	120	42234.00
349.16	42	14664.72	330.35	126	41624.10
361.96	48	17374.08	301.79	132	39836.28
370.87	54	20026.98	262.95	138	36287.10
378·45	60	22707.00	212.49	144	30598.56
383.73	66	25326.18	145.75	150	21862.50
387·22	72	27879.84	69.15	156	10787.40
389·97	78	30417.66			

and applying the column of resulting products to the formula, we shall have

Extreme Products.	Even Products.	Odd Products
00000.00	1070.46	2658.24
10787.40	4611.06	6849.12
	9334.50	11970.36
10787.40 = Σ	14664.72	17374.08
	20026.98	22707.00
	25326.18	27879.84
	30417.66	32754.12
	35091.00	37184.64
	39107.82	40724.64
	41830.02	42234.00
	41624.10	39836.28
	36287.10	30598.56
	21862.50	
		312770.88
	321254.10	2
	4	
		625541.76 = 2 s
	1285016.40 = 4 S	

and since $\frac{i}{3}$ = 2, we further have

$$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (10787.4 + 1285016.4 + 625541.76) \times 2 = 3842691.12 \; . \; . \; . \; . \; (M'')$$

Fourthly, to determine the moment of the part comprised between the sections 1″ and 5″

Semivertical areas between sections 1″ & 5″.	Multipliers.	Resulting products.
69.15	156.0	10787.40
49.72	157.5	7830.90
31.21	159.0	4962.39
15.05	160.5	2415.52
5.60	162.0	907.20

and applying the column of resulting products to the before quoted formula, we have

Extreme Products.	Even Products.	Odd Product.
10787.40	7830.90	4962.39
907.20	2415.52	2
11694.60 = Σ	10246.42	9924.78 = 2 s
	4	
	40985.68 = 4 S	

And, since one-third of the common interval = 0.5, we shall have

$$(\Sigma + 4\,S + 2\,s)\frac{i}{3} = (11694.6 + 40985.68 + 9924.78) \times 0.5 = 31302.53 \; .\;.\;.\;. \; (M''').$$

Lastly, to determine the moment before section 53, we have,

$$13.7 \times 163.5 = 2239.95 \; .\;.\;.\;. \; (M'''').$$

If now we refer to the position of the primitive vertical plane to which all the preceding moments have been referred, we shall perceive that M and M′ are on one side of it, and M″, M‴, and M⁗, on the other: and that if we denote the mean semidisplacement by D, we shall have for the distance of the centre of gravity of displacement from the primitive plane 1, the expression

$$\frac{M'' + M''' + M'''' - M' - M}{D} = \frac{3842691.12 + 31302.53 + 2239.95 - 4282.83 - 1476.66}{50488.96}$$

= 76.66 feet, which is the distance of the centre of gravity from the primitive vertical plane 1.

The preceding investigations respecting the displacement have been conducted on either of the suppositions that the ship and the water are at *rest*, or of a ship and the water moving in *the same direction with the same velocity*, in which case the ship is still relatively at rest. But when the ship and water are relatively *in motion, either by the ship being at rest and the water in motion*, or by the *ship's moving* and the *water's being at rest*, or by *the ship and water moving with unequal velocities*, or in *different directions*, the depth to which the ship sinks must be determined in connexion with other considerations. As a proof of a difference in the two conditions of a vessel alluded to, we may adduce the observations of M. Romme, that a frigate which was lashed to a sheer hulk in the river Charente, sunk two inches more when the velocity of the stream was great than when the motion of the stream was only just sensible.

In an ingenious disquisition on this subject, Mr. Morgan, one of the foremen of Portsmouth Dockyard, adduces another remark of Romme on the same subject, in which that learned foreigner describes some experiments he made to determine the vertical pressure of water when in motion compared with its pressure when at rest. He had two tin tubes constructed, the one, Fig. 4. Plate CCCCLXXXVIII, straight as *a b*, and the other curved as *c d e*, each open at its ends, and capable of receiving a float *g f*, the lower part of which, *f*, was of cork, and the upper part a rod marked with inches and lines. These tubes, containing their floats, were first plunged into still water, and the division of the rods observed, corresponding with the upper orifices of the tubes. The tubes were then placed in running water, the current being in the direction *h i*, and the bent tube *c d e*, with its lower end turned in the same direction: the floats in both tubes were then observed to have sunk an inch below the position they had when the tubes were in still water. The bent tube was then turned so as to present its orifice to the current, when the float rose an inch above the position which it had in still water. The bent tube was then placed with the lower end perpendicularly to the direction of the current, when the float sunk an inch below its position in still water. He measured the velocity of the current, and found that the water ran 70 feet in 30″, or that its velocity was that due to a height of an inch and a line nearly; which corresponded with the distance the floats in the tubes rose or fell in the experiments. Other experiments in currents of different velocities produced similar results. In some instances the depression and elevation of the floats were as much as five or six inches, being always the height due to the velocity of the current. He ascertained also that the results were the same, to whatever depth the tubes were plunged into the water.

Suppose the depth to which the tubes are plunged into the water to be represented by k; then the vertical pressure of the water at the orifice b of the straight tube, when the water is at rest, is in proportion to this depth, and causes the water in the tube to rise to the level of the surrounding water; but when the water moves with a velocity due to the height z, the particles no longer press equally in all directions, but have a greater tendency to motion in the direction of the current than in any other; so that the vertical pressure of the particles at the orifice b is less than before, and by the experiment is found to be proportional to $k - z$.

In the application of the result of this experiment to a floating parallelopiped, whose sides are perpendicular, and whose upper and lower surfaces are parallel to the water's surface, the pressure of the water on the sides being horizontal, has no effect in supporting its weight; and the vertical pressure of the particles of the water on the lower surface, being less when in motion than when at rest, in the proportion of k to $k - z$, k being in this case the perpendicular distance of the lower side of the body from the water's surface, and z as before, the height due to the velocity of the current, the parallelopiped will sink deeper in the running water, than in the still water, in the same proportion: that is, the perpendicular depth of the immersed part of the body will be $k+z$, having sunk deeper the distance z.

When the bent tube *c d e* is placed with its lower end in the direction of the stream *h i*, the effect is the same as with the straight tube; the particles of water at the orifice *e*, pressing less on the particles in the tube when the water is in motion than when at rest, the water in the tube is not equally supported; so that it sinks below the level of the surrounding water, a distance found by the experiment to be equal to z, the height of the water in the tube being $k - z$. The effect is the same also when the lower end of the bent tube is placed perpendicularly to the current; but when placed with its orifice presented to the direction of the current, the particles of the water in motion exert a pressure at the orifice *e*, greater than they would when at rest, in consequence of the velocity in the direction of their motion, which causes the confined water in the tube to rise above the level of the surrounding water, a height found by the experiment to be equal to z, the altitude of the water in the tube being $k+z$.

Now as the water rose a distance z above the level of the surrounding water, when the lower end of the bent tube was placed exactly in the direction opposed to the current, and fell the same distance z below the level of the surrounding water, when the lower end of the tube was placed perpendicularly to the direction of the current, there must be an angle at which the tube might be placed with respect to the direction of the current, at which the water in the tube would be at the same height as the surrounding water. Taking any line v in the direction of the current to represent its velocity, which is wholly effective in raising the water in the tube, when placed in the opposite direction to the current the distance z, and which has the effect of depressing the water in the tube the same distance z; when placed perpendicularly to the direction of the current, the angle at which the tube must be placed, in order that such a part of this velocity may be effective in causing the water in the tube to rise exactly to the level of the surrounding water, may be found by supposing that at this angle the effective part may be equal to $\frac{1}{2} v$, which, by the resolution of the directions of the pressures, makes the angle at which the tube must be placed 60° with the direction of the current.

In the application of this reasoning to the determination of the vertical pressure of the water in motion on a ship's body, the pressure on the fore and after parts of the body must be considered separately; the greatest transverse section called the midship section, being the division between these parts.

The expression representing the pressure of the water on the fore part will be composed of two terms, the one expressing the pressure on the part of the body where it is greater than it would be if the body were at rest, and the other the pressure on the part of the fore body, where it is less than it would be if the body were at rest. The line of division, which we will call the neutral line, being the line on the fore part of the ship's body, at which the pressure of the water is neither increased nor diminished by the velocity of the water, will be a curved line, depending on the form of the ship's body, but always before the greatest transverse section. In regular figures, its position and form may be determined either geometrically or analytically; but in ships, can be found only by trial and calculation. In the expression for the pressure of the water on the part of the body contained between the neutral line and the midship, the pressure represented by the proportional depth k will be increased by a function of z; in the expression for the part of the fore body contained between the neutral line and the midship section, the pressure represented by the proportional depth k will be diminished by a function of z: and in the after body, $k-z$ will be the element representing the pressure.

Let $a\,b$, Fig. 5. Plate CCCCLXXXVIII, represent an element of the ship's body, and $c\,b$ the direction of the motion and the height due to the velocity of a particle of water, which meets this element. By resolving $c\,b$ into $c\,d$ and $d\,b$, $c\,d$, which is perpendicular to $a\,b$, is supposed to be destroyed, and the particle of water glides along the surface of the ship's body with a velocity $d\,b$. Let $c\,b$ be equal to z, and the depth of the particle below the surface of the water be equal to k, and the angle $a\,b\,c$ equal to i: then $d\,b = z . \cos . i$. The pressure of the particle of water on the part of the fore body before the neutral line will then be proportional to $k + z . \cos . i$; the pressure of the particle of water on the part of the fore body between the neutral line and the midship section, will be proportional to $k - z . \cos . i$: and the pressure of the particle of water on the after body will be proportional, according to the experiment on the bent tube, to $k-z$.

Suppose the ship to be placed with its fore part opposed to a current, the direction of which is that of the ship's keel, and the velocity that which is due to the height z. Suppose the surface of the ship's body below the surface of the water to be divided into an infinite number of small surfaces; let x be the horizontal distance of one of these small surfaces from the midship section, and y its transverse distance from the longitudinal vertical plane, dividing the ship into two equal and similar parts, and k its distance from the plane of floatation. The projection of this small surface on the plane of floatation is $d\,x . d\,y$: and representing the specific gravity of the water by P, the pressure of the water on this small surface, in a vertical direction, in the after body, $P\,d\,x . d\,y . (k-z)$; and the vertical pressure of the water on a small surface, in the part contained between the midship section and the neutral section in the fore body, is $P\,d\,x . d\,y\,(k-z . \cos . i)$: and the vertical pressure of the water on a small surface in the part of the fore body before the neutral section, by taking x for the distance of this small surface from the neutral section, is $P\,d\,x . d\,y . (k+z . \cos . i)$. The vertical pressure of the water on the whole of the fore part of the ship's body (taking both sides of the ship), is therefore

$$2\,P \int d\,x \int d\,y . (k + z . \cos . i)$$
$$+ 2\,P \int d\,x \int d\,y . (k - z . \cos . i):$$

and the vertical pressure of the water on the whole of the after part of the ship's body, is

$$2\,P \int d\,x \int d\,y . (k-z).$$

The sum of these terms,

$$2\,P \int d\,x . d\,y . (k+z . \cos . i) + 2\,P \int d\,x \int d\,y . (k-z . \cos . i)$$
$$+ 2\,P \int d\,x . d\,y . (k-z),$$

is the total vertical pressure of the water on the ship's body, lying opposed to a current, whose velocity is that due to the height z.

If the water were at rest, the total vertical pressure of the fluid on the ship's body, supposed to be sunk to the same depth below the surface of the water, taking z for the whole length of the ship, would be $2\,P \int d\,x \int d\,y\,k$. In this expression x is equal to the sum of the three lengths expressed by x in the former expression. This quantity representing the vertical pressure of the water on the ship's body when at rest, is evidently greater than the quantity representing the vertical pressure of the water on the ship's body when in motion, in consequence of the first term of the expression $2\,P \int d\,x \int d\,y . (k+z . \cos . i) + 2\,P \int d\,x \int$

$$d\,y . (k-z . \cos . i) + 2\,P \int d\,x \int d\,y . (k-z),$$

which is less than the sum of the two other terms, being increased in a less proportion by the addition of

z . cos. i to k, than the sum of the last two terms is diminished by z . cos. i being subtracted from k in the first, which is the smaller of the last two terms, and by z being subtracted from k in the last term. The vertical pressure of the water, therefore, being less on the ship's body when placed in a current than in still water, estimated to the same draught of water in both cases, the ship must sink deeper in the current than in still water. The distance it sinks depends on the value of z, the height due to the velocity of the current, and i, representing the different angles at which the particles of water strike the ship's body, which depend on the form of the body. Supposing the values of all the terms known, and subtracting the expression for the vertical pressure of the water in motion on the ship's body, from the expression for the vertical pressure of the water at rest, estimated at the same draught of water in both cases, the remainder will be the quantity to be taken from the expression for the vertical pressure of the water at rest, measuring from the line of floatation downwards, which determines the distance which the ship will sink deeper in the water in motion than at rest.

This expression represents the vertical pressure of the water, under the consideration that each particle of the fluid in motion impinges on the surface of the ship's body; neglecting the circumstance of those particles which meet the body at the middle of the fore part, escaping along the surface of the body, and preventing many of the particles farther removed from the middle from impinging on the surface, and communicating their action to the body only, through the medium of those particles in contact with it; the particles still farther removed from the middle, communicating in the same manner their action to the body through the medium of a greater number of intervening particles. The investigation is conducted with immediate reference to the results of the experiments with the tubes, instead of forming an independent theory on the hypothetical action of fluids on floating bodies. The division of the fore part of the ship's body into two parts, by the section at the lines on the surface of the body, at which the effect of the pressure of the water in motion is the same as that of the pressure of the water at rest, is introduced by the writer of these remarks, as being directed by the results of the experiments with the bent tube; considering that the whole pressure of the water on the fore part is not increased by the motion of the fluid, but only the part before the neutral section, the pressure on the remainder being diminished.

The vertical pressure of the water on the ship's body may be determined on the same principles, but with more difficulty, when the direction of the ship's length makes any angle with the direction of the current of the water.

It may be observed, that the alteration occasioned in the vertical pressure of the water in consequence of the relative motion of the ship and water, affects the determination of the stability of the ship, which is measured by the vertical pressure of the water multiplied into the distance it acts from the longitudinal axis passing through the centre of gravity. The connexion of the common theory of the stability of ships, however, with this principle, although requisite for the direct determination of the absolute stability of a ship under sail, is by no means necessary for the determination of the comparative stability of ships, which is generally required to be known.

ON STABILITY.

The general question of stability involves considerations of the highest importance, both to the theory and practice of naval architecture. We owe our first general conceptions of its nature and properties to Archimedes,* who, in his celebrated inquiries respecting Hydrostatics, first pointed out the nature of the force which a fluid exerts to restore a floating body, when deflected from its quiescent position to its original condition. The same inquiry in the hands of Bouguer,† of Euler,‡ of Chapman,§ and of Atwood,‖ has been very much extended; and by the labours of the last mentioned philosopher in particular, it has been placed in the clearest and most satisfactory point of view.

Without entering into the general circumstances of floating bodies, (for a masterly investigation of which we refer our readers to the papers of Mr. Atwood just quoted,) we may remark, that when a vessel is floating on the surface of the water, it is impelled *downwards* in a vertical line passing through its centre of gravity, the fluid at the same time exerting an equal and contrary force *upwards*, in the direction of a vertical line passing through the centre of gravity of the portion of the vessel immersed. Unless, therefore, the vertical lines representing these forces coincide; or, in other words, unless the centres of gravity of the entire vessel, and of the part immersed, are situated in the *same* vertical line, a tendency will be created in the vessel to revolve about an axis, until it finds a position in which it can float in a state of permanent equilibrium.

Supposing, therefore, a vessel to float in a state of permanent equilibrium, and an external force to be applied, to cause it to incline from this position, a certain degree of resistance, dependent on the general circumstances of the vessel, will be created, and which resistance is commonly denominated the stability of floating.

We know also from our ordinary experience, that some bodies are more easily inclined from their positions of equilibrium than others; and that varieties equally remarkable exist in their returns to their original situations. This, indeed, is a circumstance most remarkably exemplified in the practice of naval architecture. In some ships, a given impulse of the wind will produce an inclination much more considerable than in others; and hence correct notions respect-

* Archimedes de Insidentibus Humido.

‖ Atwood on the Stability of Ships, contained in the Philosophical Transactions for 1796 and 1798.

ing the general properties of stability, must be regarded as one of the most important elements of shipbuilding.

The first and most essential point to be obtained, is an expression or measure for the force of stability at any angle of inclination. This was first attempted by Bouguer, on the supposition that the vessel was inclined at an infinitely small angle: but his investigation, although applicable to bodies of all magnitudes and forms, when their deviations from a state of permanent equilibrium are limited to evanescent inclinations, is for that reason inapplicable to the rigid purposes of naval architecture, on account of the angles to which ships are inclined by the force of the wind and the sea, amounting to quantities very considerably removed from an evanescent state. Suppose, for example, the angle of inclination to amount to ten or twenty degrees, or as it sometimes does to thirty degrees; then will conditions be involved in the investigation, which will invalidate entirely any theorem founded on infinitesimal relations. This will be evident, by referring to the conditions of the immerged and emerged volumes, produced by the inclination of the vessel. Those volumes in the formula in question, are to be regarded as similar and equal; whereas the form of a ship, both above and below the water line which corresponds to the position of permanent equilibrium, presents no such equality. Nor is this a mere hypothetical objection, but one of the highest practical importance; since it is known that the quantity of sail which a ship is enabled with safety to carry, as well as the use of her lower deck guns in rough weather have a most material connexion with the form of the sides, above and below the plane of the water section corresponding to the position of permanent equilibrium.

To put the subject, however, in a clear and satisfactory point of view, let there be two vessels of the same weight, and let the planes of their water sections be also similar and equal: but let the sides of one of them have an inclination *outwards*, both above and below the water section, as in Fig. 4, Plate CCCCLXXXIX; and the sides of the other a similar inclination *inwards*, as in Fig. 5. Now, it is manifest, without the aid of any calculation, that, notwithstanding the assumed coincidences of the weights and of the forms and areas of the water sections, the stability of the first body must be much more considerable than that of the second; and that a quantity of sail which might be productive of no material inconvenience to the former, would to the latter be hazardous and destructive. Hence, as Mr. Atwood very properly observes in the first of his papers before quoted, "admitting that the theory of statics can be applied with any effect to the practice of naval architecture, it seems necessary that the rules to be investigated for determining the stability of vessels, should be extended to those cases in which the angles of inclination are of any magnitude likely to occur in the practice of navigation."

To determine the necessary formula, therefore, when the angle of inclination is of some definite magnitude, let ABC, Fig. 13. represent a transverse vertical section of a vessel, passing through its centre of gravity G, and therefore at right angles to the axis of motion. Let I A B L denote also the plane of the water section, dividing the solid into two portions, one *above* the water's surface, but not represented in the figure, and the other ACB *below* it. Let O also be the centre of gravity of the immersed volume, and join OG, and produce it to K, and which, from the conditions of hydrostatic equilibrium, must be at right angles to the plane of the water section.

Suppose, in the next place, a force to be externally applied to the solid, so as to cause it to move through any finite angle KGS, round the axis of motion before referred to; and let the line KC, which in the state of equilibrium was vertical, now assume the position of SGL. Let also IXN denote the new situation assumed by AXB, and WRMNP, the new position of the immersed volume, in consequence of the inclination. In the line SL take GE equal to GO; then it is evident that O, the centre of gravity of the immersed volume ADHB, will be transferred to E, the centre of gravity of the equal space IRMN; and the action of the fluid on the immersed volume, would be in the direction of a vertical line passing through E, if IRMN represented the volume immersed in the fluid. But from the inclined position of the solid, the volume NXP, which in the original position of the solid was *above* the fluid surface, is now immersed in it; and, on the contrary, the volume IWX, which in the position of equilibrium was surrounded by the water, in the new position, is elevated above it. Hence it follows, that the new condition of the solid will cause the centre of gravity of the immersed volume to approach towards that part of it which is most immersed in the fluid.

Suppose, therefore, the centre of gravity of the immersed volume WRMP to be situated at the point Q, and through Q draw FS parallel to GO, or which is the same thing, perpendicular to the plane of flotation. Through E and G, draw EY and GZ parallel to the last mentioned plane. Then since Q is the centre of gravity of the volume immersed, the pressure of the fluid will act in the direction of the vertical line QS, passing through that centre, with a force equivalent to the body's weight: and by the principles of mechanics, will have precisely the same effect to turn the solid round its axis, as if the same force was applied immediately at the point Z, and acting in the same direction QS. Since, therefore, the effect of the fluid's pressure acting in the direction of a vertical line passing through the centre of gravity Q, no way depends on the absolute position of that point, but on the horizontal distance between the vertical lines GO and SF, which pass through the primitive centre of displacement and the new position of that centre created by the circumstances of inclination, it follows, that in any attempt to determine the stability of a floating body, our object must be to determine the magnitude of the line GZ.

The volume immersed under the conditions of inclination being WBMP, is manifestly equal to the volume immersed under the original circumstances of hydrostatic equilibrium, diminished by the trilateral space IWX, and augmented by the trilateral figure NXP. But since the volume immersed must always preserve the same constant magnitude as long as the whole weight of the body subjected to examination remains unaltered, and which, in every inquiry of the kind, is a necessary and essential condition, it follows, that whatever may be the position of the point of intersection X, the trilateral areas before alluded to must be equal. Having made these few general observations, we proceed to the following construction for the purpose of determining the magnitude of GZ.

CONSTRUCTION.

Find a and d the centres of gravity of the spaces IWX and NXP; and from those centres, let perpendiculars $a\,b$, $c\,d$ be drawn to the fluid surface; and in the line EY, take ET a fourth proportional to the whole volume immersed WRMP, the trilateral area IWX or NXP, and the distance $b\,c$ between the perpendiculars demitted from the centres of gravity a and d. Through the point T thus found, draw FTS parallel to GO, intersecting GZ in Z. Then will GZ represent the measure of stability.

METHOD OF CALCULATION.

Let the total volume immersed be represented by V, and the volume NXP immersed in consequence of the inclination by v. Let also the distance GO = GE, between the centres of gravity of the entire body, and of the volume immersed, be denoted by α, and the sine of the angle of inclination KGS to radius unity, by φ. Let also the distance $b\,c$ between the perpendicular $a\,b$ and $d\,c$ be represented by β. Then by the construction

$$V : v :: \beta : \frac{\beta\, v}{V} = ET:$$

and since EG : ER :: 1 : φ,

or α : ER :: 1 : φ,

we have ER = $\alpha\,\varphi$;

$$\text{whence } RT = ET - ER = \frac{\beta\, v}{V} - \alpha\,\varphi.$$

$$\text{or } GZ = \frac{\beta\, v}{V} - \alpha\,\varphi \text{ - - (A)}$$

which is a general formula for the stability of a floating body of any magnitude and form, at any finite angle of inclination.

DEMONSTRATION.

It is demonstrated by the writers on mechanics, (Wood's *Mechanics*, art. 178, third edition,) that in any system of bodies given in position, if the situation of one of them be changed, the corresponding motion of the common centre of gravity estimated in any given direction, will be to the motion of the centre of gravity of the part of the system moved, estimated in the same direction, as the weight of the body moved is to the weight of the whole system. In the present instance, the volume IRMN may be regarded as a system of bodies, whose common centre of gravity is E. The centre of gravity a of one of the bodies IWX composing this system, is transferred, in consequence of the inclination of the entire body, to the point d, the centre of gravity of the equal volume NXP. Then since the translation of the volume IWX has occasioned a motion in its centre of gravity from a to d, and which estimated horizontally on the plane of flotation, is $b\,c$; by the mechanical theorem quoted, the entire volume WRMP, is to the volume IWX or NXP, as $b\,c$ to ET; which is the measure of the space the centre of gravity of the entire volume has passed through, when estimated in the same horizontal direction. If therefore a vertical line FTS be drawn through the point T, it must also pass through the centre of gravity of the immersed volume; and since the line ER is known in terms of the radius GE or GO, and the sine of the angle of inclination EGO, it follows that by subtracting its value from ET, there will remain RT, or its equal GZ, the measure of the stability required.

We shall now proceed to apply the formula just determined to the case of a vessel whose sides are parallel to the plane of the masts, both above and below the plane of flotation.

Let QBOAH, (Fig. 14.) represent a vertical section of the vessel, when it floats in an upright or quiescent position, BA denoting the plane of flotation. Let also G be the centre of gravity of the entire body, and E that of the portion immersed in the fluid. Let V as before represent the magnitude of the volume immersed.

Bisect the line BA passing through the plane of flotation in S; and through S draw CSH, forming with BA an angle equal to the vessel's inclination. Then since BSC is the triangular area raised *above* the fluid surface, in consequence of the inclination, and ASH the similar and equal surface depressed *below* it from the same cause; bisect BC and AH in the points F and N. Join FS and NS, and take SI to SF, and likewise SM to SN in the ratio of 2 to 3; then will I and M be the centres of gravity of the triangular spaces. From these centres, let fall IK and ML perpendicular to CH. Through E, draw EV parallel to CH, and take ET to KL, in the ratio of the volume ASH to the whole volume displaced. Through G draw GU parallel to CH, and through T the line TZ perpendicular to GU, and GR parallel to TZ. Then will RT or GZ be the measure of the vessel's stability.

To determine the value of GZ analytically, and thence numerically, let BA, the breadth of the water section be denoted by $4\,b$, and GE the interval between the centres of gravity of the entire body, and of the volume immersed by α; also the angle of inclination ASH by φ. Then $1 : 2\,b :: \tan.\varphi : 2\,b\tan.\varphi =$ AH, whence $AN = b\tan.\varphi$, and $SN = b\,(4 + \tan.^2\varphi)^{\frac{1}{2}}$. Also, as SN : HN :: sin. NHS : sin. NSH; or as $b\,(4+\tan.^2\varphi)^{\frac{1}{2}} : b\tan.\varphi :: \cos.\varphi : \dfrac{\sin.\varphi}{(4+\tan.^2\varphi)^{\frac{1}{2}}}$. Hence $\cos.\,NSH = \dfrac{\cos.\varphi + \sec.\varphi}{(1+\tan.^2\varphi)^{\frac{1}{2}}}$. Now $SM = \dfrac{2}{3}SN = \dfrac{2\,b}{3}(4+\tan.^2\varphi)^{\frac{1}{2}}$; and therefore $SL = \dfrac{2\,b}{3}(\cos.\varphi + \sec.\varphi)$. And since the triangles SLM, SKI are equal and similar, $KL = 2\,SL = \dfrac{4\,b}{3}(\cos.\varphi + \sec.\varphi)$. Also the area of the triangle $ASH = 2\,b^2\tan.\varphi$. Therefore by the mechanical theorem referred to in the demonstration,

$$V : v :: KL : ET,$$

$$\text{or } V : 2\,b^2\tan.\varphi :: \frac{4\,b}{3}(\cos.\varphi + \sec.\varphi) : ET,$$

$$\text{and hence } ET = \frac{8\,b^3\tan.\varphi\,(\cos.\varphi + \sec.\varphi)}{3\,V}.$$

Also because $GE : ER :: 1 : \sin.\ \varphi$,

therefore $ER = a \sin.\ \varphi$;

whence $RT = GZ = \frac{8\,b^2}{3\,V} \tan.\ \varphi\ (\cos.\ \varphi + \sec.\ \varphi) -$ $a \sin.\ \varphi$, is the analytical value of the proposed vessel's stability.

To determine the value of G Z numerically, let the breadth of the vessel at the water's surface, or AB be 100, and the interval GE between the centres of gravity of the entire body, and of the volume immersed be 13; that is, let $b = 25$, and $a = 13$. Suppose also the angle of inclination $\varphi = 15°$; and let V the area of the section of the volume displaced be represented by 3600. Then we shall have

$$\cos.\ \varphi + \sec.\ \varphi = \cos.\ 15° + \sec.\ 15° = 2{\cdot}0012020$$

$$\frac{8\,b^3 \tan.\ \varphi}{3\ V} = \frac{125000 \tan.\ 15°}{3 \times 3600} = 3{\cdot}1012639$$

$$\text{Hence } ET = 2{\cdot}0012 \times 3{\cdot}1012 = 6{\cdot}2062555$$

$$\text{and } a \sin.\ \varphi = 13 \sin.\ 15° = 3{\cdot}3646470$$

which gives the measure of stability $GZ = 2{\cdot}8416085$

From this result therefore it appears, that when the proposed vessel has been inclined from its position of permanent equilibrium through an angle of 15°, the action of the fluid to restore it to its quiescent position, will pass at the distance of 2·84, estimated horizontally, when the breadth of the water section is denoted by 100. And this result will be the same whatever be the length of the axis.

The absolute pressure of the fluid, is in reality the total volume displaced by the body. Suppose this quantity to be 1000 tons. Then since by this hypothesis, the stability of the vessel, when inclined at an angle of 15°, is equivalent to the force of 1000 tons, acting at the distance of $\frac{2{\cdot}84}{10000}$ parts of the breadth of the water section from the axis, to restore the vessel to its primitive state of equilibrium; the effect will be the same as if a force $\frac{1000 \times 2{\cdot}84}{50} = 56{\cdot}8$ tons were applied to turn the vessel at the distance of 50 from the axis.* If therefore the wind should act on the sails of the vessel with a force of 56·8 tons, at the mean distance of 50 from the axis, the force of stability would just balance it, so as to preserve an equilibrium, the vessel still preserving its inclination of 15°.

Such is nearly the method pursued by Mr. Atwood, to illustrate the general question of stability: and we have introduced the example to the attention of our readers, to enable them to form some idea of the mode pursued by that celebrated man in this very interesting inquiry. It would very far exceed the limits of the Encyclopædia, to follow him through all the cases and forms of bodies he has chosen to illustrate his subject; but we will endeavour, by tabulating some of his leading results, to afford our readers every assistance we are able on so important a question. We recommend, however, most earnestly to every one interested in the inquiry the two papers of Mr. Atwood contained in the *Philosophical Transactions* for 1796 and 1798.

The object of Mr. Atwood in the investigation, of which the results are recorded in the preceding table, was to estimate the effects produced on different bodies, by assuming different forms for their sides; and for this purpose he preserved all their other elements constant. Thus, as the table illustrates, the breadth of the water section was in all cases denoted by 100: the distance of the centre of gravity of the entire body, and of the volumes displaced by 13: the area of the section of the volume displaced by 3600, and the angle of inclination of the constant magnitude of 15°. In the two last columns will be found the measure of stability for the different forms.

The table furnishes several remarkable conclusions. For example, by comparing the results of No. 6. with No. 8. the singular fact is disclosed, that if two isosceles wedges having their surfaces inclined at the same angle, have also the same breadth at the water's surface, and the distances between their centres of gravity, and of the volumes displaced equal, as also the weights of the bodies themselves, then will the stabilities of the two bodies, when inclined to the same angle from the upright, be always the same. The same principle may also be remarked by comparing the form No. 2. with No. 9. and likewise No. 3. with No. 10.

But the circumstance here adverted to possesses a much more general character, it being equally true, whatever be the nature of the figure assumed for the sides, provided the surfaces *below* the water line in one vessel, are *similar equal*, and *similarly disposed* with respect to the water section, to the sides of another vessel *above* the same section. This remarkable property may be demonstrated as follows:

Let QCHO, Fig. 15, represent a vessel, the sides of which *above* the plane of the water section project *outwards*, and the sides *below* the same plane *inwards*, the vessel in this position being in a state of permanent equilibrium. Suppose the vessel to be deranged from that position by the action of any force, and let CH be the position of the water's surface, in consequence of the inclination. Let also ASH

* The results contained in the preceding table are those obtained by Mr. Atwood from theory, by means of his general formula, $GZ = \frac{g\,n}{V} - a\,\varphi$; but as some of our readers may feel gratified by an experimental illustration of the truth of the same formula, we throw into this note an abstract of a paper published by Colonel Beaufoy, in the *Annals of Philosophy* for February 1824.

The apparatus employed by the Colonel was described originally in the *Annals* for March 1816, and as it may be useful to others engaged in the same interesting branch of experimental inquiry, we add a description of it.

In Plate CCCLXXXIX. Fig. 20, A, A represents a cistern filled with water, and mounted to a convenient height upon framed legs; B a model on which the experiment was tried, by attaching a fine line *a a* to the top of the mast D, and conducting it over a pulley, E. A scale F is suspended to the end of the line for the reception of the weights. These cause the model to incline, as the figure shows; and the degree of inclination of the mast from the perpendicular is shown by the plumb line *b*, upon a divided arch *d*. To prevent the body from being drawn away towards the pulley E by the draft of the line *a*, it is retained by two small lines (shown dotted at *g*, *g*,) which are made fast to sliders, *s*, *s*, at the side of the cistern, and have hooks at the opposite ends, which take hold of pins projecting from the stem and stern of the model B; and these are previously adjusted so that the centre of gravity of the model will be found in a line between them. The manner of making this adjustment is shown in Fig. 21. which represents a frame of wood, H, supporting two small uprights *h*, *h*. These have pieces of brass plate at the upper ends, with notches to receive the pins or pivots of the model B. These pivots are fitted into grooves, in two pieces of brass plate attached to the ends of the model. One of these slips of brass is shown separately at Fig. 22. where *k* is the pivot, and *l* a screw tapped into the brass slide to which the pivot is fixed, and passing through the same groove by means of this screw, the pivot *k* can be fastened at any part of the groove, and raised or lowered. The ballast is then raised or lowered till the model will barely rest on the pivots without overturning, as shown in Fig. 21. It is necessary, in order to know exactly what weight is applied to the top of the mast D, that the line *a* draw in a direction at right angles thereto. To ascertain this, a ruler, *m*, is fixed upon the top of the mast, and the pulley E is attached to a cross rail H, which applies against the uprights, and is suspended by a line *n*, which passes over a pulley, and is made fast to a cleat *o*. By this means the pulley E can at pleasure be raised or lowered until the direction of the line *a* corresponds with the ruler *m*. The manner of conducting the experiment is as follows: The cistern is filled with water up to a certain mark; and the model being put in, loaded with ballast, the water is added or decreased till the edge of the gunwale is exactly on a level with the edge of the cistern, as ascertained by applying a straight ruler, or looking across it. The plumb line *d*, cutting the zero of the divided arch, shows the vessel to be upright. In this state the model is ready for making the experiand SBC be the equal areas produced, the former being immersed in the fluid, and the latter elevated above it; and let M and I be their respective centres of gravity.

Suppose now the entire body to revolve round the line AB as an axis, and to perform half a revolution or 180°; then will the positions of its sides be entirely reversed; those parts of them which in the original

ment. The hooks of the two strings *g*, *g*, attached to the pivots and the two sliders *s*, *s*, are raised or lowered to make the strings *g*, *g* horizontal in the water. Weights being now put into the scale F, will show what weight is requisite to incline the model. The pulley E being raised or lowered by the line *n*, as is found necessary to make the line *n* draw parallel to the ruler *m*, or perpendicular to the mast. The inclination of the mast is shewn by the plumb line *b*, cutting the divisions of the arch *d*; but to counteract the weight of the plummet *b*, which tends to incline the mast, another counterbalancing plummet and line *r*, is applied to the opposite side of the model. For this purpose holes are made on the arch *d*, at every division, and a peg is put in at the division opposite to that which is cut by the plumb line. The experiment is tried with different weights, to produce the several inclinations at every five degrees, until 30 degrees from the perpendicular; and to verify the experiment, the model is changed end for end, the strings *g*, *g* being hooked on the pivots at the opposite ends. In this way the series of trials are made on the opposite side, by which means, if there is any difference in the two sides, or in the ballast, it will be detected, and allowed for by taking the mean of the different trials.

The bodies employed by Colonel Beaufoy were of different forms, measuring in breadth ten inches, and in length fourteen inches, or within a few hundredths of an inch of fourteen. The immersion in water was four inches, or two-fifths of the width. The total depths were various, those bodies whose sides projected outwards requiring greater depth than those with sides inclining inwards. The bodies to be referred to are, Figs. 1, 2, 3, &c. Plate CCCCLXXXIX.

As in the account of Atwood's investigation in the text, so in the experimental inquiry of Colonel Beaufoy, AB represents the breadth of the water section, and CH the surface of the water when the vessel is inclined. In the first set of experiments, the centres of gravity of the entire body, and of the volume immersed, were supposed to coincide in the point E, in which case ET represents the measure of stability. But in the second series of experiments the former centre was elevated above the latter 1.3 inches, or $\frac{13}{100}$ of the breadth of the water section, making GZ, as in Atwood's inquiry, the representative of stability. By producing TZ to meet EG produced, the point of intersection M becomes the metacentre of the body.

If from the total depth of each model the distance of the centre of gravity of each from its bottom be subtracted, the remainder will be the distance of the centre of gravity from the upper surface. If therefore to this distance be added the constant length of the mast, the sum will be the length of lever to which the different weights were applied to produce the desired inclination of the model. And since the momentum of the water acting on the inclining vessel must be equivalent to the momentum of the inclining power, it follows that, by calling w the inclining weight, L the length of the lever at which it acts, and W the weight of the displaced volume of water, in the first series of experiments we shall have $ET \times W = L \times w$, whence $ET = \frac{L \times w}{W}$; and in the second series $GZ \times W = L \times w$, whence $GZ = \frac{L \times w}{W}$, the values of the lines ET and GZ, being, as before remarked, the respective measures of the stability in the two sets of experiments.

To illustrate these formulæ, let the first experiment with the first model be selected from the following Tables, and let the angle of inclination be 5°. Then the total depth of the model being 7.1 inches, the distance of its centre of gravity from its bottom two inches, and the constant length of the mast 20.96 inches, it follows that $L = 7.1 - 2 + 20.96 = 26.06$ inches. And to produce an inclination of 5°, it appears, by the first horizontal column of the table, that a weight of 2.2239 ounces applied at the extremity of the above length of lever is necessary; hence $w = 2.2239$; also $W = 324.52$ ounces, and we derive from the formulæ $ET = \frac{L \times w}{W} = \frac{26.06 \times 2.2239}{324.52} = .18$, for the length of lever at which the displaced volume of water acts, to restore the body to its vertical position.

In the following tables, the results of the two series of experiments are recorded. In the first horizontal column is entered the weight of water displaced by the model; in the second, the length of lever at which the inclining power acts, and in the third, the distance of the centre of gravity of the model from its bottom. In the first vertical column is recorded the several angles at which the model is inclined; in the second, the weights necessary to produce those inclinations; in the third, the values of ET and GZ, the distances at which the displaced volume of water acts, to restore the body to its vertical position; in the fourth column, the values of the same lines calculated by the formula of Atwood; and in the last column, the elevation GM of the metacentre, above G the centre of gravity of the body, calculated by the trigonometrical proportion,

Sin ∠EMT : ET or GZ : : radius : EM or GM.

It may be proper to remark again, that in performing the experiments after the vessel had been inclined on one side, it was turned and then inclined the other, by which means any error in the distribution of the ballast, or in the position of the mast could be corrected, by taking the mean of the results deduced from the opposite positions. The difference, however, Colonel Beaufoy remarks, seldom amounted to two drachms, and, in general, was much less.

position of the body projected *outwards*, *above* the water's surface, in the new position, inclining *inwards*, *below* the same surface; and the other parts of them which in the position of permanent equilibrium inclined *inwards* being now found inclining *outwards*. Let Fig. 16. denote this new condition of the body, and *c h* the position of the fluid surface, when the solid is inclined to the same angle as denoted by Fig. 15. Now since AB=*a b*, it follows that ABCO being applied to *a b c o*, so that the point A may coincide with *a*, AB with *a b*, and consequently the point B with the point *b*, the two sections will be identical and equal in all respects. Also since the lines CH, *c h*, are equally inclined to the lines AB, *a b*, and cut off the areas ASH, *a s h*, respectively equal to the areas BSC, *b s c*, it follows when the line AB coincides with *a b*, the points S and *s* must coincide also, and likewise the areas just mentioned. As a necessary consequence, the centres of gravity M and I will coincide with the corresponding points *m* and *i*; the line ML with *m l*, IK with *ik*, and consequently KL with *k l*. And since the area ASH is equal to the area

BSC, and *a s h* to *b s c*, it follows that the four areas are equal to each other. Hence since the volume immersed, is by the supposition in each case the same, it follows that $ET = \frac{\beta v}{V}$, and $e\,t = \frac{\beta v}{V}$, and therefore $ET = e\,t$.

Now this equality between the lines ET and *e t* being independent of the positions of the centres of gravity of the entire bodies, and also of the positions of the centres of gravity of the immersed volumes, it follows that if the distances of those centres be the same, that ER will be equal to *e r*, because by the hypothesis, the angles at which the bodies are inclined are the same. If therefore from ET we subtract ER, and from *e t* take *e r*, there will remain RT or GZ equal to *r t* or *g z*; and from which we infer that the stabilities of the two bodies are the same.

Another property demonstrated by Mr. Atwood is, that when the vertical sections of one vessel are terminated by the arcs of a conic parabola, and the sides of another vessel are parallel to the plane of the masts above and below the plane of the water section, the stabilities of the vessels will be equal at all equal inclinations from the upright, when the breadths of the water sections, and all the other conditions are the same in both cases—a coincidence which could scarcely be supposed to exist in bodies so dissimilar in form.

In another case he has also proved, that if the sides of one vessel coincide with the curve of a conic parabola, and the sides of another vessel with a conic parabola of any other form, but having a different parameter, the breadths of the water sections, the weights of the vessels, and the other conditions being the same, the stabilities of the two vessels at all equal angles of inclination will be equal. This he infers from the principle, that in proportion as the dimensions of the parabolic curve are augmented, the figure more closely approximates to a sectangular parallelogram; and that when they are increased *sine limite*, the form ultimately coincides with a body of that kind. And that as we have before seen that the stability of the conic parabola is the same with that of the rectangular parallelogram, so must the stability of a body whose form is that of a parabolic curve of the highest possible dimensions, approach to the same identity. As a matter of useful reference, illustrating the remarkable property alluded to, and because the forms of vessels approximate in many cases to the parabolic figure, we insert Fig. 17, in which the curve

*c*B*C*o is a conical or appollonian parabola.
*d*BD*o* a cubic parabola.
*e*BE*o* a biquadratic parabola.
*f*BF*o* a parabola of 8 dimensions.
and *g*BG*o* a parabola of 50 dimensions.

Having made these general observations on the subject of stability, we shall in the next place proceed to the application of the principles that have been developed, to the computation of the stability of the ship whose displacement we before computed.

For this purpose let BDQA, Fig. 18, represent that portion of the principal vertical section of the vessel proposed, which is situated below the water line BA, when the plane of the masts is at right angles to the fluid surface; and let DC represent the line which coincides with the surface of the water, when the vessel is inclined at an angle of 10°, at which angle we propose to compute the stability. This plane DC, from the conditions of stability, must be so situated as to cause the *volumes immersed and emerged* in consequence of the inclination, to be equal in solidity; and it will follow, from the varieties of form which the

By a reference to the third and fourth columns of each experiment, it will appear how closely the experimental values of ET and GZ, at the different angles of inclination, approximate to the theoretical values of the same lines, deduced from Atwood's formula.

different transverse sections of a vessel present, that the areas of the figures SAbC, SBeD can in no case be equal; although, in the previous investigations, from the perfect equality and similarity supposed to exist among the transverse sections, the areas of immersion and emersion were properly regarded as equal. And it is farther evident, that at whatever distance the point S is situated from the middle point X of the water's surface, in any one section, the same distance XS will be preserved in every other section; for by the supposition the vessel is inclined round the longer axis, and therefore the intersection of the planes which pass through the lines BA and DC will be parallel to the longer axis, and consequently parallel to a line drawn through all the points X, from one extremity of the vessel to the other.

To show, in the next place, by what means the magnitude of XS is to be determined, through X draw the line XXW inclined to the water's surface at the given angle; and let a plane be supposed to pass through it, so as to cut all the sections in like manner. Then by means of the ordinary rules of mensuration, let the area of the figure AXWb be computed for each section; and from these equidistant areas, let the solidity of the volume comprised between the two planes XW and XA be calculated by means of the formula $(\Sigma + 4\,S + 2s)\frac{i}{3}$, and let the same operation be performed for the solid contained between the planes BX and XX. Let the former of these solidities be denoted by A'. Then will the difference of these solidities be equal to the solid comprised between the two planes XW and DC. And if we represent the area of the section XW by W, this difference will be equivalent to W × SO; that is A—A' = W × SO.

But by trigonometry XS : SO : : 1 : sin. SXO.
and therefore SO=XS × sin. SXO.

This value of SO being substituted in the preceding equation, gives A—A'=W×XS×sin. SXO, and from which we obtain

$$XS = \frac{A - A'}{W \times \sin. SXO}.$$

Our limits will not admit of our exhibiting the actual computations for this formula, but the result for the value of XS=.25 of a foot.

Having determined the value of this necessary and essential element, we shall proceed at once to compute the stability. In the first place, to calculate the succession of mixtilineal areas produced by the transverse sections by which the vessel has been divided, and of which series ASCb represents one of immersion, and BSDe another of emersion, we must divide each of them into a triangular area as SAC in that of immersion, and into a parabolic area as CAb, to which curve the small segment CAb closely approximates.

To compute the succession of rectilineal areas, we must obtain all the values of SA and SB, and also all those of the succession of perpendiculars, one set of which is denoted by Cc and Dd. To obtain those of SA and SB, we must, in the first place, observe, that the point S not being situated, as we have before demonstrated, in the middle of the water line, but is distant from it by the quantity XS = .25 above determined, it follows that this quantity must be subtracted from XA in one case, and added to its equal XB in the other. Now the values of XA or XB will be found in the first horizontal column of the general table in the article on the displacement, and from the numbers representing them are derived the results recorded in the second and fifth columns of the following table.

Number of the section.	Values connected with the Immersion.			Values connected with the Emersion.

To compute the areas of the parabolic segments ACb, BDe, we must bisect the double ordinates CA, BD in H and F, and draw Hb, Fe, perpendicular to them. The different values of these double ordinates, and of their corresponding abscissæ, will be found in the preceding Table.

Hence, by adding together the corresponding triangular and parabolic areas recorded in the two preceding Tables, we shall obtain the values of the entire mixtilineal areas ASCb, BSDe, as entered in the next Table:

Number of the section.	Values connected with the Immersion. Values of the mixtilineal area ASCb.	Values connected with the Emersion. Values of the mixtilineal area BSDe.	Number of the section.	Values connected with the Immersion. Value of the mixtilineal area ASCb.	Values connected with the Emersion. Values of the mixtilineal area BSDe.

Having therefore obtained the values of all the mixtilineal areas recorded in the columns of the last table, we must proceed in the next place to compute from them, the solidities of the volumes immersed and emerged. These solidities are each made up of the five following portions:

First, the solidities of immersion and emersion abaft the vertical section 5′.

Secondly, the solidities of immersion and emersion between the vertical sections 5 and 1′.

Thirdly, the solidities of immersion and emersion between the vertical sections 1 and 27.

Fourthly, the solidities of immersion and emersion between the vertical sections 1″ and 5″.

Fifthly, the solidities of immersion and emersion before the vertical section 5″.

To compute the solidity abaft the vertical section 5′, let Fig. 19. be referred to, in which ABCD represents a transverse section of the stern post and rudder, EF being a vertical line passing through the middle of the same.

Then since by the first number of the horizontal column 5″ of the general table, the semi-thickness M p of the stern post is equal to 0.75, and that O the distance of the point of intersection produced by the inclination of the vessel, is distant from M the quantity 0.25, it follows that O p = 0.75 — 0.25 = 0.5, and O q = 0.75 + 0.25 = 1.00, and from which numbers the given angle of inclination 10°; and the breadth of the stern post and rudder 5 feet, the following calculations for the solidity are derived:

Solidity of immersion abaft vertical section 5′.	Solidity of emersion abaft vertical section 5′.
O p = 0.5	O q = 1.0
p s = 0.0881	q t = 0.1763
Area s O p = 0.022	Area q O t = 0.0881
Solidity of which s O p is a section } = 0.11	Solidity of which q O t is a section } = 0.4407

In a similar way, and by a reference to the same figure, may the solidities of immersion and emersion before the vertical section 5″ be computed, M p the semi-thickness of the stern post, being, according to the first number in the column 5′ of the general table, equivalent to 0.8, the breadth of the portion of the stern being 4.5 feet.

Solidity of immersion before the vertical section 5″.	Solidity of emersion before the vertical section 5″.
O p = 0.55	O q = 1.05
p s = 0.096	q t = 0.185
Area s O p = 0.0264	Area q O t = 0.0971
Solidity of which s O p is a section } = 0.1188	Solidity of which q O t is a section } = 0.4369

To obtain the solidities of the remaining portions, recourse must be had to the general formula $(\Sigma + 4\,S + 2\,s)\frac{i}{3}$: and first, for the portions comprised between the vertical sections 5′ and 1′, the necessary elements being obtained from the last table.

SOLIDITY OF IMMERSION.

Extreme Areas.	Even Areas.	Odd Area.
0.0275	2.7160	14.7510
29.9750	23.9090	2
30.0025 = Σ	26.6250	29.5020 = 2 s
	4	
	106.5000 = 4 S	

and since $\frac{i}{3} = 1.1416$, we shall have

$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (30.0025 + 106.5 + 29.502) \times 1.1416 = 189.5107$, which is the solidity of immersion comprised between the vertical sections 5′ and 1′.

SOLIDITY OF EMERSION.

Extreme Areas.	Even Areas.	Odd Area.
0.105	2.033	8.1395
21.813	15.351	2
21.918 = Σ	17.384	16.2790 = 2 s
	4	
	69.536 = 4 S	

and the common interval being as before, makes for the formula $(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (21.918 + 69.536 + 16.279) \times 1.1416 + 122.988$, which is the solidity of immersion, comprised between the vertical sections 5′ and 1′.

The next set of calculations must be for the solidities of immersion and emersion comprised between the sections 1 and 27.

SOLIDITY OF IMMERSION.

Extreme Areas.	Even Areas.	Odd Areas.
29.975	37.4825	41.4765
12.140	43.5550	44.9860
	46.0000	47.0660
42.115 = Σ	47.9400	48.8220
	49.6080	50.4000
	50.7150	50.9250
	51.0300	51.0300
	51.0300	51.0300
	50.9250	50.7150
	50.5050	49.9200
	48.9590	47.6260
	44.3330	36.9300
	27.1070	
		570.9265
	599.1895	2
	4	
		1141.8530 = 2 s
	2396.7580 = 4 S	

And since in the present series of sections one-third the common interval is 2 feet, we have

$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (42.115 + 2396.758 + 1141.853) \times 2 = 7161.452$, which is the solidity of immersion comprised between the vertical sections 1 and 27.

SOLIDITY OF EMERSION.

Extreme Areas.	Even Areas.	Odd Areas.
21.813	30.9450	38.0320
9.225	41.8775	44.9950
	47.6010	49.1070
31.038 = Σ	50.4800	51.3870
	51.9515	52.6200
	53.6840	54.3950
	54.5040	54.5040
	54.5040	54.0080
	53.4050	52.2580
	51.6370	51.1780
	54.5920	45.9680
	40.7850	32.9520
	20.6970	
		581.4040
	606.6630	2
	4	
		1162.8080 = 2 s
	2426.6520 = 4 S	

And since one-third the common interval is 2 feet as before, we have

$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (31.038 + 2426.652 + 1162.808) \times 2 = 7240.996$, which is the solidity of emersion contained between the vertical sections 1 and 27.

Lastly, to compute the solidities between the vertical sections 1″ and 5″, we derive the following numbers from the same table:

SOLIDITY OF IMMERSION.

Extreme Areas.	Even Areas.	Odd Area.
12.140	7.875	4.064
0.025	1.314	2
12.165 = Σ	9.189	8.128 = 2 s
	1	
	35.756 = 4 S	

And since the common interval in these latter sections is 1.5 feet, we have

$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (12.165 + 36.756 + 8.128) \times 0.5 = 28.524$, which is the solidity of immersion between the vertical sections 1″ and 5″.

SOLIDITY OF EMERSION.

Extreme Areas	Even Areas.	Odd Area.
9.225	6.290	3.562
0.100	1.245	2
9.325 = Σ	7.535	7.124 = 2 s
	4	
	30.140 = 4 S	

and since the common interval is the same quantity as before, we have

$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = 23.294$, which is the solidity of emersion comprised between the vertical sections 1″ and 5″.

Collecting the results therefore of the parts just determined of the solidities of immersion and emersion into separate sums, we shall obtain

	Immersion.	Emersion.
Solidities abaft vertical section 5′	0.1100	0.4407
Solidities between vertical sects. 5′ and 1′	189.5107	122.9880
Solidities between vertical sects. 1 and 27	7161.4520	7240.9960
Solidities between vertical sects. 1″ and 5″	28.5240	23.2940
Solidities before vertical section 5″	0.1188	0.4569
	7379.7155	7388.1556

These solidities differing only from the mean of the solidities of immersion and emersion, by the quantity 4.22, may be regarded as a proof that the distance 0.25 determined for XS, is not very widely distant from the truth.

Our next object must be to estimate the moments of the solids of immersion and emersion. To accomplish this, we must obtain the centres of gravity of each of the triangular and parabolic areas before determined. For this purpose in Fig. 18, bisect AC and BD in H and F: join SH and SF, and take S*r* and S*p* each equal to two-thirds of SH and SF. In like manner, in the abscissæ H*h* and F*e* of the parabolic segments, take *hf* equal to three-fifths of H*h*, and *eg* equal to three-fifths of F*e*. Then will the points *r* and *p* be the centres of gravity of the triangular areas, and *f*, *g*, those of the parabolic segments.

Since also the effect of the moment is to be estimated with reference to the surface, of which DSC is a section, from the centres of gravity just determined, let fall the perpendiculars *rt*, *fh*, *pn*, and *gi*, on it, either by calculation or the more expeditious means of actual measurement from the working drawings, obtain the values of S*t*, S*h*, and S*n*, S*i*. These values are entered in the third, sixth, tenth, and thirteenth columns of the next table, and when multiplied respectively into the values recorded in the second, fourth, ninth and twelfth columns, will produce the moments given in the fourth, seventh, eleventh, and fourteenth columns of the same table. This, however, we will more particularly illustrate after the table is entered.

If now the moments corresponding to the mixtilineal areas ASC b, BSD c in the preceding table be applied to the formula $(\Sigma + 4\,S + 2\,s)\,\frac{i}{a}$, we shall obtain the total moments of immersion and emersion.

MOMENT OF IMMERSION.

Extreme Areas.	Even Areas.	Odd Area.
0.0091	9.9406	128.9024
369.5308	264.7485	2
369.5399 = Σ	274.6891	257.8048 = 2 s
	4	
	1098.7564 = 4 S	

and since one-third the common interval of the sections = 1.1416, we shall have

$(\Sigma + 4\,S + 2\,s)\,\frac{i}{3} = (369.5399 + 1098.7564 + 257.8048) \times 1.1416 = 1970.517$, which is the moment of the solid of immersion comprised between the vertical sections 5′ and 1′.

MOMENT OF EMERSION.

The general formula for stability before deduced being $GZ = \frac{\beta v}{V} - \alpha \phi$, gives also by clearing from fractions, $V \times GZ = \beta v - \alpha V \phi$, and under which form we shall apply it to the example now under consideration.

For this purpose, we may remark, that the first member V × GZ represents the true measure of the stability, and that by the calculations immediately preceding, and those connected with the displacement, the centre of gravity of displacement, and the centre of gravity of the entire vessel, the values of all the elements of the second member become known.

In the *first* place, the quantity βv is equivalent to the sum of the moments of immersion and emersion, or equal to 112187.0829 + 114787.6507 = 226974.7336 = 6484.9924 tons.

Secondly, The element α denoting the distance between the centres of gravity of the entire body, and of the volume immersed, is equal to the sum of the distances of those centres from the plane of the water section. The distances of the former point *above* the plane here alluded to, has already been determined to be 0.9409; and the distance of the latter point *below* the same point, has also been found to be 7.78. Hence we shall have

$$\alpha = 0.9409 + 7.78 = 8.7209.$$

Thirdly, The element V, or the displacement, has been likewise found in the article devoted to that subject to be 2885.084.

Fourthly, The value of ϕ, the natural sine of the assumed angle of inclination = 0.1736482. Consequently the expression for the stability, or V . GZ = $\beta v - \alpha V \phi$ = 6484.9924 — 8.7209 × 2885.084 × 0.1736482 = 2115.9118 tons, which is the stability of the proposed vessel, at an angle of ten degrees.

The preceding calculations for the stability will, no doubt, be regarded by our readers as long and laborious, but we were anxious to lay before them the most approved and perfect methods. It will also be perceived, that it is the rigid determination of the value of βv by the formula for equidistant areas, which is the cause of the extension of the investigation. But the computation of the stability may be much modified and shortened by adopting the metacentric method of Bouguer, and will be sufficiently accurate when only an approximate value is required.

For this purpose, let the equation of stability V . GZ = $\beta v - \alpha V \phi$ be resumed, and let our object be to determine a more convenient form of computation for the function βv.

Let ADB, Fig. 23, represent a transverse vertical section of a vessel passing through the centre of gravity of displacement, the points A and B being in the plane of the water section. Suppose now a force to be so applied to the vessel as to cause it to incline through the angle aCA, and, at the same time, to preserve a constant volume of displacement, and also a constant breadth of the water section, and let ab be the water section produced by the inclination.

Suppose, in the next place, the semi-breadth of the vessel AC or CB to be denoted by x, and the length of the water line by y. Let also the volume of displacement be denoted, as before, by V.

Then, since by the hypothesis there is no alteration of volume in the displacement, the prism immersed, and of which a section is represented by the triangle AC a, must be equal to the prism emerged, and of which the equal and similar triangle BC b is a section. From a, let ao be drawn at right angles to AC; then will the area of either of the triangles CA a, CB b, be represented by $\frac{CA \times a\,o}{2} = \frac{CA \times C\,a \times \sin. \angle\, AC\,a}{2}$ (since CA and C a are supposed equal) $= \frac{CA^2 \times \sin.\ AC\,a}{2} = \frac{x^2 \sin. \phi}{2}$, the function ϕ representing the sine of the angle of inclination as before. Hence the differential of the volume immersed or emerged in consequence of the inclination, will be $\frac{x^2 \sin. \phi\, d\,y}{2}$.

Moreover, the distances of the centres of gravity of the same volumes, estimated from the common point C, will be $\frac{2\,x}{3}$. And by a law of mechanics, the emerged prism may be supposed to be transferred and concentrated with the prism immersed; and the moment produced by the transfer will be the volume of the prism, multiplied by the distance of translation of its centre of gravity, or $\frac{x^2 \sin. \phi\, d\,y}{2} \times \frac{4x}{3} = \frac{2x^3 \sin. \phi\; d\,y}{3}$.

Hence, the general equation of stability V . GZ $= \beta\, v - \alpha\, V\, \phi$ will present the approximate form V . GZ $= \frac{2 \sin. \phi}{3} \int x^3\; d\; y - \alpha\, V\, \phi$, and by which the following computation is performed.

To determine the value of $\int x^3\; d\, y$, we must again have recourse to the first horizontal line of the general Table of Ordinates, and after taking the cubes of the elements contained in it, apply the results to the formula $(\Sigma + 4\ S + 2\, s)\, \frac{i}{3}$.

This value, reduced into tons, becomes 56186.67, and which is therefore the value of $\int x^3\ d\ y$ in this measure. But the expression in our approximative formula is $\frac{2 \text{ sin. } \phi}{3} \int x^2\ d\ y$; and which becomes, by taking the function ϕ as 10°, equivalent to 6504,4761 tons. And the value of $\alpha\ V\ \phi$ being, as before determined, 4369.0806 tons, we shall obtain for the expression

$$V\ .\ GZ = \frac{2 \text{ sin. } \phi}{3} \int x^3\ d\ y - \alpha\ V\ \phi$$
$$= 6504.4761 - 4369.0806$$
$$= 2135.3955$$

tons, the stability of the vessel according to the approximative method proposed.

Hence it appears, that the metacentric stability differs from the true stability only by 19.48 tons, or by $\frac{1}{108}$ of the whole quantity; and as the calculation by the approximative method is so much shorter and more convenient than the method of Atwood, there can be no reason why it should not be adopted, when absolute precision is not required.

It is proper, however, to remark, that there are considerable chances of error in the employment of the metacentric method, when the constructer is not well acquainted with the method of Atwood. For a knowledge of the true method of computing the stability makes us acquainted with the necessity of examining particularly the figures of the solids of immersion and emersion, which the metacentric method does not; and if the sides of a ship should be found to incline considerably inwards in those parts, the latter method would without question be inapplicable.

It is remarkable that the stability of all ships, by the metacentric method, would be the same, *cæteris paribus*, as if the sides between the immersion and emersion were circular arcs, and the stability correctly measured by Atwood's method.

The practical errors, in the cases of the Endymion and Icarus, are as follows:

	Stability by Atwood's method.	Stability by the metacentric method.	Difference. Error.
Endymion of 50 guns	1729	1736	$7 = \frac{1}{247}$
Icarus of 10 guns	208	205	$3 = \frac{1}{69\text{n'ly.}}$

Atwood adduces, as a proof of the imperfection of the French method of measuring the stability, the case of Le Scipion, built at Rochefort in 1776, and L'Hercule and Le Pluton, which were built from the same design, and were found, when launched, very deficient in this important quality. The first *ingénieur constructeur* was sent from Paris to remedy the defect, and after trying an alteration in the ballast, which was found totally inadequate to correct it, he directed a doubling of timber to be brought round the sides of the ship, from four inches to one foot in thickness, extending the whole of the ship's length, and reconciling with the curve of the body ten feet below the water's surface. This completely remedied the defect. That the stability would be increased by it, would have been equally evident, by whichever method it might have been calculated. It could not have been suggested by Atwood's method, since it was not used in France,—indeed was not known. The fault of these ships was, in a great degree, if not altogether, too sudden an inclination inward abaft the main breadth. Atwood appears to have supposed it to arise altogether from falling away too suddenly below the plane of flotation. On this rests the whole of his argument in adducing these ships as an example of the incorrectness of the French, and the correctness of his method of determining the stability of ships. Their defect might have been clearly ascertained by subjecting the design to the determination of the height of the metacentre, which would have been found much too low.

Bouguer, however, carries the theory of the metacentre much further: he says that his theory being duly investigated under the consideration of the angle of inclination being infinitely small, it is necessary to extend the consideration of it, to render it applicable to finite angles. He traces the metacentric curve as the ship gradually inclines from its upright position, and determines its nature; he says that if this curve rises as the ship inclines, the ship will be secure; but if the curve descends, that the ship will be insecure.

Atwood shows, most clearly, the error of this doctrine: he says, that "the construction and properties of the metacentric curve, being a subject of geometrical reasoning, considered purely as such, are liable neither to ambiguity nor error; but on what grounds these properties are applied to measure the stability of vessels, or to estimate their security from upsetting, when much inclined from the upright, is not explained by M. Bouguer, M. Clairbois, or any other author I have had an opportunity of consulting."

Atwood proves that the stabilities of two vessels, one of which Bouguer considers to be secure in inclining, and the other insecure, are exactly equal. His reasoning on this part of the subject appears most conclusive, and we again earnestly recommend his two papers to the particular attention of the reader.

On the Centre of Gravity of a Ship.

Like all other material systems, a ship must possess a centre of gravity, whose essential properties are the same as commonly attributed to it by the elementary writers on mechanics. The determination, however, of its exact position in a ship, is a matter of considerable difficulty, and at the present moment is to be numbered among the many desiderata of naval architecture.

Frequently important calculations are made to depend on very rude and mechanical approximations towards its true situation; and connected as this very essential element is, with so many properties of a ship, we trust that our naval engineers will not rest until they have placed it on a basis more definite and exact than it reposes at present.

The first difficulty in the way of determining the centre of gravity of a vessel in a complete state of equipment for sea, (for the determination of this point under any other circumstances, as for example when the vessel is in a state of ordinary, would not produce all that is to be desired) arises from the peculiar circumstances of *form*, and the varied and uncertain influences of the masts, yards, rigging, and other necessary parts of a ship's equipment; and secondly, from the ever-changing circumstances of lading, and the different modes of stowage, which different conditions of a vessel require.

If we direct our attention to the hull, we shall find its external figure presenting a surface of a very uncertain kind; and although mathematicians might reach, by an approximate process, the position of the centre of gravity, under the most general circumstances of form, yet from the uncertainty which hangs over the general principles of construction, but little advantage would be likely to result from it. In the British navy at the present moment, we have almost *every possible variety of form*; and as every alteration of figure necessarily involves new considerations respecting the masts and their accompaniments, and also new considerations respecting the stowage, it follows, that we cannot, without making allowances, and for which we have no precise and definite rules, apply with certainty any results that may be obtained, even to ships of that class for which the primitive calculation was made.

If we consider for a moment the peculiar figure of a ship, we may remark, that wherever the point now under consideration is situated, three rectangular coordinate planes may be supposed to pass through it; and that to one only of the three can we assign any definite position. This certainty of position with respect to one of the co-ordinate planes, arises from the symmetry existing (or which at least ought to exist) between the two parts of a ship, when it is divided by a vertical longitudinal plane, passing through the centre of the keel; and in which plane, therefore, this point must be somewhere situated. This symmetry of form, therefore, with respect to the longitudinal plane, fixes the position of the centre of gravity of a vessel with regard to its *breadth*.

But in no other direction can we suppose a plane to pass, so that the moleculæ on opposite sides of it shall be *precisely similar and equal*; a condition indispensably necessary, for determining *a priori* from the *form* of the vessel, the position of either of the other co-ordinate planes. But we may, however, fix with some tolerable approach to certainty, the position of the centre of gravity with respect to *length*, by attending to a condition which the laws of Hydrostatics furnish, that the centres of gravity of the entire ship, and of the volume of fluid displaced by its immersion, are in the *same vertical line*; and that as every vessel when equipped, possesses a *given* displacement, it follows that the determination of the centre of gravity of displacement, fixes the position of the centre of gravity of the entire ship with regard to the *length*.

But the determination of the situation of the centre of gravity with respect to the third and last dimension *depth*, is that which involves the greatest share of difficulty; and for the attainment of which, many methods have been proposed; some grounded on theoretical considerations, and others founded on experiment. One very correct but laborious method is, by calculating the momentum of every molecule constituting the ship, from some assumed horizontal plane, and dividing the integral of these moments, by the total weight of the ship. This method is founded on the well-known mechanical theorem, that if p, p', p'', &c. be particles lying on *one* side of a plane given in position, and π, π', π'', &c. particles lying on the *other* side, at the perpendicular distances x, x', x'', &c. X, X', X'', &c. respectively, then the distance of the common centre of gravity of the particles p, p', p'', &c. π, π', π'', &c. from the plane, will be

$$\frac{p\,x+p'\,x'+p''\,x''+,\&c.-(\pi\,x+\pi'\,x'+\pi''\,x'',\ \&c.)}{p+p'+p''+,\&c.+\pi+\pi'+\pi''+,\&c.}$$

where the centre of gravity will lie on the *same* or *contrary* side of the plane with p, p' p'', &c. according as $p\,x+p'\,x'+p''\,x''+$,&c. is *greater* or *less* than $\pi\,x+\pi'\,x'+\pi''\,x''+$,&c.

In the present case, the plane to be assumed is that of the water surface, and to it must be referred all the moleculæ constituting the ship; and not only must the weight of *every individual timber, yard, gun, anchor, &c. &c. &c. be obtained*, but also the *corresponding distances of their centres of gravity from the plane assumed*. This operation is of course tedious and laborious*, but must of necessity be accomplished, if we are desirous of ascertaining with the greatest possible precision the situation of this very important point.

* What Mr. Reynold said of painters, may with equal truth be said of shipbuilders. "Those who are determined to excel must go to their work whether willing or unwilling, morning, noon, and night, and will find it to be no play, but very hard labour." Perhaps the mechanical arts do not in general inspire that ardour and enthusiasm which the cultivation of the fine arts so beautifully encourage; but there is unquestionably a wider field open for honour and renown in naval architecture, than in any other branch of mechanics. We want a man of original mind, who will pursue the subject for its *own sake*, and enter on its cultivation with that energy and enthusiasm, which distinguished Brindley for canals, or Watt for the steam engine; a mind ready to seize all the good that its predecessors have achieved, and courage to attempt those plans of its own, which an enlarged and philosophical mind has so much at command. It is not too much to expect, that such a man may yet arise, to throw a new light on naval architecture, and to impart to it that improvement which so many other arts have derived from highly gifted minds.

The limits of the Encyclopædia unfortunately, will not permit us to exhibit in perfect detail the individual weights necessary for this important calculation, but we shall endeavour, by a brief, and we hope luminous sketch, to give the results, and the methods by which they are obtained.

In the first place, the different weights constituting the ship, must be divided into two classes, throwing such as have their centres of gravity *above* the plane of flotation into one class, and those *below* the same plane, into another. The former are exhibited in the first of the following tables, and the latter in table the second.

Names of the different weights *above* the water's surface.	Values of p, p', p'', &c. in Tons.	Values of x, x', x'', &c. in Feet.	Values of the moments $p\,x, p'\,x'', p''\,x'$, &c.

To explain the methods by which the numbers in the first and second numerical columns of the preceding tables were obtained, we must, in the first place, remark, that the plane to which the centre of gravity is to be here referred, is that of the water's surface; and that all the numbers recorded in the second numerical column, are to be regarded as the distances of the centres of gravity of the several weights entered in the first column, from the plane of flotation. Thus to obtain the first number, in the first table, the weights of the lower masts, the top masts, the top gallant masts, and their necessary appendages, together with the weights of all the yards, as likewise the weight of the bowsprit, were all carefully ascertained and also the distances of the centres of gravity of the same parts, from the plane of flotation. The former result gave 77·61 tons, which is the value of p in the general formula, and the latter 54·64 feet, which is the value of x. The moment of the masts, yards, &c. must therefore be $77{\cdot}61 \times 54{\cdot}64 = 4240{\cdot}6104$, which is the value of $p\,x$ in the third column of the same table. In like manner, must the weight of all the standing rigging be obtained, and also the weight of all the running rigging, divided into such portions as the judgment of the calculator may direct. This will give for the value of p', 58·56 tons; and when the distance of the common centre of gravity of the same portions is obtained, it will furnish the value of x' or 56·53 feet. The product of these, amounting to 3310·3968 or $p'\,x'$, is the value of the moment of the same. To obtain the moments of the cables, hawsers, &c. particular attention must be given to the place of stowage, in order to obtain the distance of their common centre of gravity from the plane of flotation. The weight of these articles, amounting to 40·66 tons, is the value of p'', and the distance of their common centre of gravity, from the assumed plane, amounting to 0·21 feet, is the value of x''. Their product, or 8·132 is the moment, or the value of $p''\,x''$, as recorded in the third column. The sails are estimated, when furled on their respective yards, and the spare sails as they are compactly stowed in the sailbins. The guns, a very important element in the computation, from the magnitude of their moment, must have their entire weights estimated with all their appendages, and also with equal care the distances of their centres of gravity from the assumed plane, making due allowance for the curvature of the decks. The moments also of the anchors must be estimated in their respective places of stowage, and so also must the boats, the fire hearth, the officer's furniture, the men's bedding, as stowed in the nettings, and lastly, the entire moment of the men, estimated at their quarters.

If we now pass to the consideration of the moments *below* the water's surface, as entered in the second table, our attention is first directed to the hull, the computations connected with which are very laborious and intricate. To perform the calculations with precision, the weight of each individual timber must be estimated, and also the position of its centre of gravity, whether above or below the fluid surface. Thus if we refer to the disposition of the eighty-four gun ship, plate IV. for the purpose of illustrating the operation, and take the bend of timbers at 8; marked *d, e, f, g, h, i, k, l,* and *m,* we must, in the first place, find the weight of the cross piece *d,* and then the distance of its centre of gravity below the load water plane. Afterwards the weight of the half floor *e,* on each side of the ship, and the distance of its centre of gravity; and so on for the first futtock *f* on each side the ship; the second futtock *g,* the third, fourth, and fifth futtocks *h, i, k,* the top timber *l,* and lengthening piece *m,* estimating the moments as positive, *above* the water's surface, and negative *below;* and at the same time making an allowance for the bolts and other fastenings belonging to the bend of timbers selected for illustration. Performing this operation for all the timbers, the keel, the planking, riders, beams, decks, knees, both of iron and wood, shelf-pieces, water-ways, breast-hooks—in a word, for every component part of the structure, we shall obtain the total moment of the entire hull. In the first number of the second table, the weight of the hull appears to be

1608.13 tons, which is the value of π in the general formula; and the distance of the common centre of gravity of all the individual parts amounts to 0.842 feet *below* the water line, and which is the value of x; giving for the moment of the hull 1354.0455, or the value of πx in the general formula. The water, the second particular contained in the table, must be estimated with the same minute attention to accuracy, whether contained in tanks or casks, and also the tare of the tanks or casks themselves. So also must the wood and coals, as stowed in bulk. The specific gravity of each species of provision must likewise be found, and which, by knowing the bulk of the same, and the position of the centre of gravity, will furnish the moment desired. In the same manner must the mechanical effects of the bread, as stowed in bulk in the bread room be estimated; the wine and spirits as stowed in the spirit room, the beer, the purser's slops, and the men's chests. The shot also, whether stowed in the shot lockers, or placed in the racks on the different decks; the powder and cartridges as stowed in the magazines, and the boatswain's, gunner's, and carpenter stores, as deposited in their respective store rooms.

There remains but one particular more, and that is the ballast; and to obtain the mechanical effect of which, the absolute *weights* of all the preceding articles must be selected from the tables, and their sum subtracted from the total displacement. The difference of the two will be the quantity of ballast necessary for the ship, and which amounts, in the present case, to 233.59 tons. To compute the position of the centre of gravity of the same, a plan illustrative of the mode of stowage must be carefully prepared, and the position of the point in question computed from thence. Its distance below the plane of flotation in the present case is 16.5 feet, producing, in conjunction with the weight of the ballast itself, the moment 3854.235, and which, it will be observed, with the exception of the moment of the masts, yards, and bowsprit, is the largest moment in the whole calculation.

Hence, it appears, that the sum of all the moments *above* the water's surface, or the value of $p x + p' x' + p'' x'' +$ &c. in the general formula, is 11991.9746; and the sum of all the moments *below* the water's surface, or $\pi x + \pi' x' + \pi'' x'' +$ amounts to 9277.37. Also the value of $p + p' + p'' +$ &c. . . . . . . $+ \pi + \pi' + \pi''$ &c. is the total displacement, or 2885·084 tons. Hence the general formula,

$$\frac{p x + p'x' + p'' x'' + \text{\&c.} - (\pi x + \pi' x' + \pi'' x'' + \text{\&c.})}{p + p' + p'' + \text{\&c.} + \pi + \pi' + \pi'' + \text{\&c.}}$$

becomes $\frac{11991.9746 - 9277.37}{2885.084} = .9409$ feet;

which is the altitude of the centre of gravity of the entire vessel, when completely equipped, *above* the plane of flotation. The centre is known to be *above* the plane of the water's surface, because the value of $p x + p' x' + p'' x'' +$, &c. exceeds $\pi x + \pi' x' + \pi'' x'' +$ &c. in the general calculation.

Such then is a general view of the process of obtaining the centre of gravity of a vessel, by estimating the moments of all its parts; an operation that was performed with the greatest industry and zeal by several students of the School of Naval Architecture, and from whose interesting results the preceding computations, with some alterations, have been derived.

It is obvious, however, that the method which has been just explained for determining the centre of gravity of a vessel, cannot on every occasion be adopted with convenience, although its accuracy and value renders it desirable, that it should be employed whenever circumstances will permit. Accordingly, different experimental plans have been proposed for determining this important point, one of which we shall now explain to our readers.

1°. "Let the ship's company be separated and placed on the decks, quarter-deck, and forecastle, either on the middle, or divided on both sides of the ship, so that it does not incline. Let all the guns be run out above and below; place the quadrant, by which the inclination of the ship is to be measured, and observe the ship's draught fore and aft."

2°. "Mark the situation of the gun carriages on the deck."

3°. "Haul in the guns either on one or both decks as far as the hatches and other hindrances will allow, some more and others less, till the ship has acquired an inclination of about six or eight degrees. Nail cleats against the trucks of the carriages, that they may stand fast. Let the men take their former stations and observe exactly how many degrees and minutes the ship inclines."

4°. "Number the guns, and measure the distance that each of them has been moved."

5°. "Take the weight of each gun, carriage, breeching, and coins, &c. that follow the gun when moved, and reduce this weight to cubic feet of sea-water."

6°. "Multiply the weight of each gun, &c. by the distance moved, which is the momentum of that gun."

If then we refer to the general formula of stability,

$$V \times GZ = \beta v - \alpha V \varsigma,$$

we shall find that the element we are desirous of determining is α, and whose value is represented by the equation.

$$\alpha = \frac{\beta v - V \times GZ}{V \varsigma}.$$

all the members of which being necessarily known by the conditions of the investigation, gives the distance of the centre of gravity of the ship, from the centre of gravity of displacement; and the position of the latter point being known from other investigations, will determine the situation of the centre of gravity of the ship.

The experimental method here described was originally proposed by Don Juan in 1771, although it has been commonly attributed to Chapman. Another method, however, has been proposed by Mr. Major in the Annals of Philosophy for June, 1826, which is so very neat and ingenious, that we insert it for the information of our readers.

Let the ship be heeled to the same angle by two separate horizontal forces, applied at different heights in the plane of the masts. Then it is evident that the momenta of the forces which result from the separate applications of the inclining forces must be equal, since the same constant force of stability represents them both. Let P represent one of these forces, and p the other; and let a and b be their respective distances of action from the centre of gravity of displacement; let also Δ be the angle of inclination of the ship from the perpendicular, and x the distance of the centre of gravity sought, from the centre of gravity of displacement. We shall then have the following equation of condition for the forces employed:

$$P(a-x)\cos.\ \Delta = p(b-x)\cos.\ \Delta,$$

$$\text{or } Pa - Px = pb - px,$$

$$\text{whence } x = \frac{Pa-pb}{P-p},$$

and from which we derive the following simple practical rule:

"Divide the difference of the momenta of the inclining forces from the centre of gravity of displacement, by the difference of the same paces, and the result will be the distance of the centre of gravity of the displacement.

Having now illustrated the method of determining the position of the centre of gravity, we shall consider what effect the total force acting at this point produces on the pitching and rolling of a ship, two considerations of great moment in the structure of a vessel.

To estimate in some degree, these effects, suppose ADB, Fig. 24, to represent the transverse section of a ship, AB being the section of the same plane with the water's surface, E the centre of gravity of the entire ship, and G the metacentre. Suppose, moreover, a force to be so applied at B, in the direction BH, as to produce an inclination denoted by the line *a b*. Then, by the principles of mechanics, the moment of the effort producing the inclination will be in proportion to EH, the distance between the centre of gravity and the point where the direction of the inclining force meets the axis DH; and the moment of the effort which tends to restore the ship to its upright position, is in proportion to EG, the interval between the centre of gravity and the metacentre. Now, since these efforts act in opposite directions, there results a motion, termed *rolling*; and the total effect of the forces producing it, is as the sum of EH and EG. And since the ship, during the act of rolling, ought to revolve round *a common longitudinal axis*, and not at different inclinations about *different axes*, a property, however, by no means easily to be obtained, but which we shall advert to again hereafter: and that its weight or displacement is supposed to be the same at all inclinations as when the vessel is situated in its upright position, a condition, however, which cannot happen, unless the ship, and consequently its centre of gravity E, be elevated a quantity, the value of which we shall now endeavour to exhibit.

Chapman in his naval architecture, supposes the quantity here alluded to, to be the versed sine of the angle GE *g* to the radius EG; but Dr. Inman, in a judicious note on the subject, properly remarks that this cannot be the case, and illustrates his position as follows: By inspecting, says he, Fig. 25, it will be seen that, supposing G to be fixed, the immersion must *exceed* the emersion. Through Y, therefore, the middle point between A and B, draw RYV parallel to *a b*; then, if RV were the water's surface, the immersion RYA would be equal to the emersion VYB. If, therefore, the surface of the water descends through XZ, the versed sine of the angle at G to the radius GX; or, which is the same thing, if the point G rise through the same line XZ, the displacement will remain unaltered. This, Dr. Inman observes, must be true at any inclination whatever, if the sides between wind and water be shaped as represented in this figure; but if the sides be not parallel to the plane of the masts, the above reasoning will be true only when the inclination is evanescent, or, in a practical sense very small.

Hence it appears that the versed sine of the angle alluded to, must be in proportion to the radius EX, Fig. 24. supposing X to be the point where EG cuts the surface of the water, and then it is limited to the condition of evanescent inclinations.

When the effort whose influence has produced the inclination has ceased, the ship will *fall* by the action of gravity through the height E *e* alluded to; and which fall is moreover accelerated by the action of the fluid on the metacentre G. As the rolling may sometimes extend as far as thirty degrees on each side, the magnitude of E *e* must be considerable, and it becomes a very important point, therefore, in the construction of a ship to guard against it. And to do this, Dr. Inman recommends the position of the centre of gravity to be found by computation, and then to alter the body, *till the immersion and emersion caused by heeling round a quiescent longitudinal axis passing through that point are the same.*

For this purpose, let G, Fig. 26. be the centre of gravity of a body whose transverse section is AOB. Draw GX at right angles to the load water line, and also GY, making with XG an angle, XGY, equal to any proposed inclination. Take GY equal to GX, and through Y draw *a* Y *b* at right angles to GY; then will *a b* be the load water line when the ship is inclined, and BS *b*, AS *a*, the prismatic solids, which are denominated those of immersion and emersion. If the contents of these are found to be unequal, the body must be altered and the solids recomputed, till they are found to be as nearly equal as possible.

The easy rolling of a ship round the longitudinal axis alluded to, depends, in the first place, on the position of the centre of gravity of the ship; and secondly, on the form of the sides of the vessel between wind and water. This will be apparent by referring to Figs. 25, 27, and 28, each of which represents the body of a ship whose sides are parallel to the plane of the masts, A *b* the surface of the water, A B the load water line in its upright position, and G the centre of gravity of the ship supposed equally distant from A B and *a b*. In the first of these figures, G, the centre of gravity, is supposed to be *below* the plane of the water's surface; in Fig. 27, the same point is supposed to be *coincident* with the same plane; and in Fig. 28 it is above it. At an angle of inclination of ten degrees, AS *a* is to be regarded as the *immersion*, and BS *b* the *emersion*, the axis of rotation passing quiescently through the point G.

Now, by an inspection of these Figures we may remark, that in Fig. 27, the ship, in the act of rolling, *will neither rise nor fall*, because the solids of immersion and emersion are the same; but in Fig. 25, the immersion being greater than the emersion, the ship will *rise* in heeling; whereas, in Fig. 28, the ship will *fall* when rolling, because the immersion is less than the emersion.

If, in Fig. 27, the sides were made to fall out above the load water line, it is manifest, supposing the axis of rotation quiescent, that the immersion would exceed the emersion. In such a case, therefore, the ship would rise. In Fig. 25, also, if the sides above the load water line fell out, the immersion would exceed the emersion in a greater degree than before, and produce a proportionate elevation of the ship. And if the same thing were to take place in Fig. 28, the immersion being greater than before, the falling of the vessel would be diminished. In all these cases, the longitudinal axis is supposed quiescent.

If, again, the sides of a ship fell out below the water, preserving their parallelism to the plane of the masts above it, the ship represented by Fig. 27 would fall in heeling, the rising of that represented by Fig. 25 would be corrected, and the falling of that denoted by Fig. 28 increased.

We may hence perceive how much the form of a vessel between wind and water influences her rolling; and, as a general principle, it may be observed, that the motion of rolling is more uniform, and more free from sudden shocks, when the centre of gravity of a ship is in or near the plane of the load water section. And as this position of the centre of gravity exercises the same influence in regard to pitching, which is rolling lengthways, it follows that the position of the centre of gravity alluded to, is that which is proper in both cases. If, however, other circumstances do not admit of the centre of gravity being situated in the plane referred to, every endeavour should be made to bring it as near to it as possible. It may also be further added, that as the keel, and the lower parts forward and aft, which are the cleanest, contribute greatly to the diminution of the rolling by the direct opposition of their surface to the water, the farther these parts are situated from the axis of rotation, the greater will be the effect they produce in diminishing the rolling. For the same reason, likewise, when the centre of gravity is in the plane of the load water section, the ship should roll less.

There is a curious and interesting view of the subject of rolling sometimes taken, of regarding the successive changes of position of a ship, as analogous to the oscillations of a heavy body influenced by the constant action of a gravitating force operating at its centre of gravity.

The writers on mechanics have shown, that the distance of the centres of oscillation and suspension, of a body vibrating by its own weight, may be found, by dividing the angular inertia of all its particles, that is, the sum of the products of each particle into the square of its distance from the axis of rotation, by the whole body multiplied into the distance between the said axis and the centre of gravity. Thus, if p, p', p'', &c. denote the particles of a ship, and d, d', d'', &c. their respective distances from the axis of rotation which passes through the centre of gravity, and M the entire mass of the ship, the length of such an isochronal pendulum will be

$$\frac{p\,d^2 \times p'\,d'^2 \times p''\,d''^2 \times \text{\&c.}}{\text{M.EG}}$$

where EG measures the interval between the centre of suspension and the metacentre, the whole buoyancy of the fluid, or its equivalent, the entire weight of the ship, acting upwards on the latter point G.

If we suppose all the terms $p\,d^2$, $p'\,d'^2$, &c. of the numerator given, as well as the mass M of the denominator, it is evident that the length of the isochronal pendulum will vary inversely as EG; and from which it follows, that the greater the distance of the metacentre from the centre of gravity of the ship, the shorter must be the representative pendulum, and the quicker will be the vibrations of the ship. The less, moreover, that distance is, the slower will the rolling become.

If we suppose again, the length of EG to be given, as also the mass of the ship, the times of vibration will vary as the quantities d, d', d'', &c. which represent the distances of the particles of the ship from the axis of rotation. The less also these distances are, the shorter will be the pendulum, and the quicker the rolling. The greater these distances are, the slower will be the periods of rolling.

The above reasoning, however, as Dr. Inman properly remarks, is only strictly true when the vibrations are evanescent; but may be regarded as nearly true when they are in a practical sense very small. When a ship rolls through finite angles, the vibrations differ considerably from those of a pendulum of an invariable length. For the point G, where the vertical axis passing through the centre of gravity, may be supposed to be acted on by the mean buoyancy of the fluid on righting the vessel, is not then a fixed point. Nor can any precise or general conclusions be drawn from the expression for the length of the isochronal pendulum, respecting the degree of quickness or slowness of the vibrations, as depending on the length of EG. What, however, is thence concluded respecting the position of the weights, is true for any angles of rolling. The farther they are situated from the longitudinal axis passing through the ship, the greater will be their inertia, and the greater also the resistance the ship opposes to an inclining power. It may be proper, therefore, in cases where the stability is too little, to have recourse to such an arrangement of the weights, care being taken, however, to keep them at the same distance below the surface of the water.

Nothing is more difficult, as Chapman observes, than to construct a ship, so as to unite the qualities of sufficient stability and easiness of rolling; since any increase of the distance between the centre of gravity of the vessel and its metacentre, increases the stability, and adds at the same time to the rolling of the vessel. If the stability be diminished, a greater inclination will be produced by a given force. The inclination and righting of the ship, however, will be slower and more easy, because the force producing the motion will be overcome more gradually, and the parts of the ship will, as a consequence, be in a less degree strained. At the same time it is manifest, as Dr. Inman remarks, that the stability cannot be too much diminished, without compromising the service of the ship, and even endangering its safety.

Again, Dr. Inman remarks, that an increase of stability has the effect of rendering the angle of inclination less; and so far it is useful: but carried to excess, the inclining force would be destroyed so suddenly, that the shock might be dangerous. The effect also of the stroke of a wave on the side, the breadth being supposed to be increased, for the purpose of giving additional stability, would become greater; so that a ship thus constructed, would in the least sea be subject to incessantly quick vibrations. And in this important particular, Chapman seems to have erred, when he considers the height of the metacentre *alone*, as a sufficient criterion of the properties of a vessel with respect to its easiness or vivacity of rolling. This, indeed, cannot be the case, unless the angles of rolling are regarded as absolutely evanescent. It is possible, as Dr. Inman farther remarks, that the height of the metacentre may be sometimes diminished, and yet by an attention to the form of the sides, the stability may be made sufficiently great. It is possible, on the other hand, that the height of the metacentre may be increased beyond the quantity usually assigned to it, and yet by injudicious alterations in the sides, the stability be found too little.

To form a proper estimate of a ship's properties in this respect, it is necessary, during the formation of her plan, to make accurate calculations of her stability at different angles of inclination, and to compare the result in each case with the stability of approved ships of the same class. So that to enable the constructer to plan ships, which might be expected to answer fully in point of stability, he must be furnished not only with various calculations on all kinds of ships which have been previously built, but also with a minute detail of their performance at sea.*

The difficulty also of establishing a proper relation between the stability and the property of rolling, is still farther increased in ships like our merchantmen, in which it is desirable to unite economy of construction with the capability of stowing the greatest possible cargo. Ships of this kind, as Chapman remarks, should be very full below, and have but little height above the water in proportion to their breadth. A ship of this kind also, should have its centre of gravity of displacement very low, and which would also have the property of bringing the metacentre low likewise. On this account it is necessary to bring the centre of gravity of the cargo as low as possible, in order that the ship may have sufficient stability. The consequence, however, of such a construction will be, that the ship will be subject to quick rolling, and violent shocks, which, however, may be partly diminished by *winging* the weights as much as possible. The rolling of ships of burthen is however favoured by another circumstance, namely, that for economy it is necessary to navigate them with as few men as possible, a circumstance that renders a less quantity of sail necessary, and diminishes the interval between the centre of gravity and the metacentre.

In ships of war the centre of gravity may be higher, and the position of the metacentre should be such as to bring the common centre of gravity of the ship and weights, as nearly as possible into the plane of flotation. In the British navy, the height of the metacentre above the surface of the water is generally less than 6 feet. In eighteen gun brigs, it is 5.5 feet. In thirty-six gun frigates, it is nearly 6 feet. In the Leopard, a fourth rate, it is 4.2 feet. In third rates it varies from 4 to 5.5 feet; and in the Howe, a first-rate of 120 guns, it is 3.7 feet. Its altitude is, therefore, the greatest in the smallest ships, and *vice versa*.

Having now seen that the centre of gravity of a ship, in regard to *height*, should be as nearly as possible coincident with the plane of flotation, it will be our next object to consider its position with regard to the length. On this head we shall follow the steps of Chapman.

As the length of a ship is very great in proportion to its breadth, the metacentre, with regard to the former dimension, will be considerably elevated, particularly in ships which have a full load water line, and are very lean under the water fore and aft. The length of the isochronous pendulum will in consequence be exceedingly great, especially, if by placing the weights near the extremities, the point of suspension is situated very low.

The rolling of the ship according to its length is such, that its extremities rise and fall; a motion produced by the raising of the fore part of the ship by a wave, and which is immediately succeeded by a depression of the same part the moment the wave has passed. This motion would cease immediately, if wave did not succeed wave with rapidity, and thus continue the effect. When a ship is close to the wind and meets the waves, and after a sea has passed the forepart falls suddenly, and raises itself with difficulty upon the following wave, the ship is said to *pitch*. When the after part falls heavily, the ship is said to *scend*. Both these effects very much impede the sailing, and prodigiously affect the masts. The whole frame, moreover, labours and works exceedingly.

The cause of the pitching and scending arises from the waves passing with rapidity the forepart of the ship, and when arrived at the middle part, leave the forepart unsupported. The ship necessarily precipitates itself into the void, with a momentum proportional to the rectangle of the weights in the forepart, and their distance from the point where the ship is sufficiently supported.

This kind of motion is greater in ships which are very full near the load water line fore and aft, and very lean below. If the weights in the fore part are carried nearer the middle, the momentum with which the ship plunges itself in this part will be less; and not only will this motion become less quick, but the succeeding waves which meet the fore part of the ship, will have less difficulty in raising it again. And a similar observation applies to the after part.

Hence it follows that all the weights should be brought as near as possible to the middle of the ship; and, therefore, that the centre of gravity with respect to the length, ought to be also at the middle point. This, however, though theoretically correct, cannot be practically exemplified on account of the weight of the foremast and its rigging, the bowsprit, the anchors, and the stores necessarily placed forward. And hence Chapman concludes that *the centre of gravity should be placed before the middle of the length, but not more than between a hundredth and a fiftieth of the length.*†

In every investigation of this kind, however, we should remember that the centre of gravity of the load water line and the centre of gravity of the ship should be in *the same vertical line;* for when the ship sails close to the wind, and is inclined on one side, if the load water line is fuller aft than forward, since the displacement must remain constant, it will have an inclination also forward. On this important point, Dr. Inman remarks, that when a ship floats upright,

* What an extensive and important field of inquiry, therefore, would be opened by a digest of the properties of the most approved ships of the British navy; and how earnestly is it to be desired that the same may be speedily undertaken, under the liberal auspices of our public boards.

† The length in Swedish construction is taken between two perpendiculars to the keel. That at the stern is drawn from a point on the after side of the stern post at the height of the wing transom at the middle line. That forward is drawn from a point on the foreside of the stern at the same height above the water line with the wing transom.

the centres of gravity of the ship and the displacement are at the same distance from the stern. When the ship is inclined, the latter point is carried to leeward, and in consequence the buoyancy of the water, supposed to act upwards through it, tends to turn the ship back. The axis round which the ship will then revolve, depends on the position of the centre of gravity of the displacement after the inclination. If it be in the transverse section passing through the centre of gravity of the ship, (which is supposed in all disquisitions on this subject) the vessel will be made to roll round an axis parallel to its length; since, in that case, there cannot be any tendency to roll round a transverse axis passing through the centre of gravity.

But if the centre of gravity of the inclined displacement be behind or before the said transverse section, in that case the buoyancy will cause the ship to revolve round a transverse axis as well as round a longitudinal one; in other words, it will cause the ship to revolve round a diagonal axis,—a motion that must tend to disunite the parts of the ship, to derange its adjustments, and operate considerably in retarding its progress.

It seems desirable, therefore, Dr. Inman continues, to keep the centre of gravity of the displacement, as the ship inclines, in the transverse section in which it is placed, when the ship floats upright. This may be effected by taking care in the construction, that the line joining the centres of gravity of the immersion and emersion, at least at common angles of heeling, be parallel to that section. For the motion of the centre of gravity of the displacement takes place in consequence of the removal of the emersion, and the addition of the immersion, which is equal in bulk to the emersion; it may be considered, therefore, as produced by transferring the emersion collected in its centre of gravity to the centre of gravity of the immersion. And by a well-known principle of mechanics, if this transfer be made along a line *parallel* to the transverse section, the centre of gravity of the whole system, or of the whole displacement being once in the plane of that section, must always remain so.

When a ship sails by the wind, that is, when the wind is on the side of the ship, or more ahead, then almost all vessels have such a form, that they will of themselves, without the aid of a rudder, turn the stem more towards the wind, because the mean direction of the water's resistance passes usually a little before the centre of gravity of the ship.

If this resultant passed too far ahead, it would be an inconveniency which might be remedied, by giving a greater draught of water aft. The greater the velocity of the ship, the more sensibly this effect is felt, and the vessel can then be kept to her course only by the constant action of the rudder.

ON THE RESISTANCE WHICH A SHIP IN MOTION MEETS WITH FROM THE WATER.

We come now to the consideration of a subject, embarrassed with difficulties of no ordinary kind, and which will continue to retard the advancement of naval architecture, so long as its primary laws remain imperfectly developed. The resistance of fluids has engaged the attention of some of the profoundest philosophers; and when we mention that the labours of Newton, of Huygens, of Euler, of Daniel Bernoulli, of D'Alembert, of Don Juan, of Bouguer, of Condorcet, of Borda, of Bossut, of Chapman, of Clairbois, and of many others, have furnished us with little more than theories distinguished for ingenious speculation, and examples of the beauty and power of analysis, with few, if any practical maxims to guide the constructer in the choice of the primary elements of his ship, our readers will only join us in regretting, that a subject so intimately connected with the progress of naval architecture, should yet be so entirely in its infancy, and so far removed from any thing like practical perfection.

In the Annals of Philosophy for December 1824, Mr. Harvey has remarked, in a paper on this interesting subject, that had the subject been one which "*individual* industry and sagacity could have successfully prosecuted, there can be no doubt but its complete solution would have been long ago achieved, or at least some large and important steps made towards its completion. But, unfortunately for the sake of science, and for the naval service of the country also, this is not the case. "The problem," says he, "is one which involves too many difficulties for any individual to contend with, unless that individual possessed talents of the very highest order, uninterrupted leisure, and the necessary command of money"—"three elements," says Mr. H., "not often united in the same person; and as the past has not afforded a fortunate example of the kind, we may almost fear the future will not be more propitious."

It is perhaps true, as the author of the foregoing quotation has remarked, that the completion of the problem of resistances will scarcely be accomplished by individual talent and industry; but it is more than probable that the germ of a correct theory, whenever it appears, will be the result of individual sagacity and thought. It certainly opens a curious and interesting field of inquiry, why so much *apparently* well-directed labour should have produced so little that is of practical importance and value; and why, at a period, when so many other departments of physical science have attained to such high comparative perfection, the science of Hydrodynamics should yet be involved in so much uncertainty and error.

A careful analysis of all the theories that have been offered on this important subject, and of the experiments on which they are founded, the circumstances also under which these experiments were performed, together with the peculiar views of their authors, bringing all to the test of the known and established principles of Mechanics and Hydrostatics, might perhaps unfold to us some of the causes that have retarded its advancement. Such a review would, at all events, as Mr. Morgan has remarked in one of his papers on Naval Architecture,* be "most likely to lead to some practical results, by ascertaining what is fairly and certainly established: and by showing the merits and defects of the different theories, be the means of determining the propriety of adopting parts of some theories, which, as wholes, may be inadmissible." Such a review, if attended with no higher

* Papers on Naval Architecture, No. I. p. 29.

benefits, "would at least have the advantage, by an acquaintance with what has been written on the subject, of preventing the unnecessary labour of retracing the steps of others; either leading to the further investigation of a theory, from a point to which it is arrived, or suggesting researches in other directions."*

But a remark† has been lately thrown out respecting this subject, by the Academy of Sciences of Paris, —a body which has done more to encourage theoretical and experimental inquiries on this question, than any other learned society in Europe,—that "almost all the attempts which have hitherto been made for discovering the laws of the resistance of fluids, are contrary to the first rule of experiments, by which we ought to endeavour *to decompose the phenomena into their most simple elements.* It has been most common indeed, to observe *the time employed by different bodies, in describing a given space in a fluid at rest, or the weight which keeps in equilibrium a body exposed to the impulse of a fluid in motion.* But this can only make us acquainted with the *total result* of the *different actions* which this fluid exerts *upon each of the points of the bodies, actions which are very varied, and often opposite to each other.* In this state of things, *compensations* take place, *which mask the primitive laws of the phenomenon,* and which render the results of experiment *inapplicable to any other case but that which has furnished them.* M. Dubuat, author of the *Principes d'Hydraulique*, appears to have been the first who perceived this defect; and, in order to avoid it, he endeavoured to measure the *local pressures* on the *different parts* of the surfaces of bodies exposed to the impulse of a fluid in motion. His experiments, though small in number, and not much varied *in so far as the form of the body is concerned*, present, nevertheless, many curious results. Under these circumstances, the academy thought it would be useful to resume these experiments, with more perfect instruments, to multiply them, and to vary the circumstances still more. And in following up these important views, the academy has proposed for the subject of a prize,‡ the following programme:

"To examine in its details the phenomena of the resistance of water, by determining with care, by exact experiments, the pressures *separately* sustained by a great number of points, properly chosen in the anterior, lateral, and posterior surfaces of a body, when it is exposed to the impulse of a fluid in motion, and when it moves in the same fluid at rest; to measure the velocity of the water in different points of the current near the body: to construct from the results and observations, the curves which these currents form;§ to determine the point where their direction commences before the body; and finally, to establish, if possible, from the experimental results, empirical formulæ, which might be afterwards compared with the experiments formerly made on the same subject." Let us hope that these new experiments may be attended with all the advantages desired to naval architecture.

Having made these general observations, in order to put our readers in possession of the real state of our information respecting the resistance of fluids, and its applications to the science of naval architecture, we shall offer a few remarks from Chapman, in order that our readers may become acquainted with the views of a man, who, if he did not possess the highest philosophical qualifications, nevertheless, from the great attention he devoted to naval architecture, and the efforts he made to blend science as much as possible with its practical details, is entitled to considerable attention.

When a ship is at rest, observes Chapman, the pressure of the water upon each of its extremities is the same; but as soon as it is impelled by any force, the pressure is increased at the end opposite to the impulse, and is diminished at that end where it acts.

Again, if a plane be moved in the water, the resistance is the most forcible when the direction of the motion is perpendicular to the plane, and becomes less as the plane assumes a position more oblique to the line of motion. Hence bodies of different forms and convexities, with equal bases, experience different resistances.

It is by no means difficult to estimate the resistance which one body meets with from another, when impinging on it: but the difficulty becomes prodigiously increased when the object is to determine the effect which any medium produces on bodies moved therein. The effect of the impact of bodies on each other is subject to known mechanical laws; but that of media upon solid bodies, is, as we have before remarked, almost unknown.

When a body is at rest in water, every part of it immersed in the water, is subject to a pressure perpendicular to its surface, and the degree of pressure produced is some function of the depth of the part subject to the action of the fluid. This is a fact verified by daily experience.

When a ship, Fig. 29, Plate CCCCLXXXIX, is put in motion in still water, with any velocity, it always happens that the water upon the extremity A before the greatest breadth C, rises against this part, above the surface at F. This elevation is perceptible at some distance before the ship in the direction of its course. It also extends laterally towards PQ: but beyond the greatest breadth C, the water *falls* again,

* Some steps towards a review of this kind have been made by Morgan and Creuze, in the useful work before quoted. In the first number is given an abridged translation of the theory of Don Juan, an author who united in his ingenious and useful work on the Theory of Seamanship, a rare combination of much that is useful both in theory and practice. In the second number is given a translation of the Abbé Bossut's Report on the Experiments made on the resistance of Fluids by D'Alembert, Condorcet, and the Abbe Bossut. We hope to see this excellent plan followed out in the succeeding numbers, and concluded by a general review of the whole subject.

† See Dr Brewster's Journal of Science, No X. p. 368.

‡ The prize will be a gold medal of the value of three thousand francs, and will be adjudged on the first Monday of June 1828. The memoirs must be sent to the secretaries of the Institute before the 1st of January 1828.

§ The late Admiral Sir Charles Knowles made many beautiful experiments for determining the paths of the filaments of water. At a certain distance from the body subjected to the action of the fluid, he allowed small jets of a coloured fluid which had no tendency to *mix* with water, to enter the fluid. The experiments were performed in a vessel having a glass bottom and sides. A luminous taper was placed several feet above, in order to throw the shadows of the coloured filaments on a white plane held below the bottom of the vessel, and on which the projected shadows of the various curves were accurately traced by a pencil.

so that between C and B it is below its proper level, until it meets in D the part of the fluid which constantly follows the ship with the same velocity as itself, in order to fill up the void space which it would otherwise leave behind. But as the water which glides along the side of the ship has already filled this space, there is a collision in the fluid in EE, which produces what is called *eddy water*. This is a thing most observable in small vessels, which draw little water; but in large ships the elevation of the water before is not perceptible till they have attained a velocity of 4 or 5 feet in a second. This water, which is before the greatest breadth, is driven forward with the ship, and so moves in the same direction; and as it is higher before the greatest breadth than abaft, it flows down a declivity, so as to acquire a velocity in a direction contrary to that of the ship: and moreover, the greater the velocity of the ship, the greater is this declivity.

All this may be readily observed when a ship is navigated in a sea but little agitated; but when a vessel sails in a channel where there is not more than three or four times the breadth of the ship between it and the sides of the channel, the effect is much more perceptible, however small may be the velocity.

Hence it follows that the resistance a ship sailing with a given velocity meets with, is increased on account of the water's rising before the greatest breadth, and because the ship has to propel a more elevated body of water before it, than at the commencement of its motion; although this column thus elevated and driven a-head, by acting on the water in the direction of its motion, before the body of the ship gets to the same point, in some degree diminishes the resistance.* *Secondly*, that the resistance is farther increased, because the water is lower behind the greatest breadth, and because this water has, moreover, lost in regard to its pressure against the after part of the ship, a force which depends on the velocity of the ship, and also on that with which the fluid flows along the after part of the ship, in running from the greatest breadth of the ship to the stern post.

We shall now proceed to illustrate the method employed for estimating the resistance of ships, by supposing ACBQ, Fig. 30. to be a body formed of two wedges, joined together at their base CQ, the pressure of the water on which, perpendicular to the surface, is denoted by FG, FG.

Suppose, in the next place, the body to move with the velocity FH, in a direction parallel to the middle line AB, from B to A. Complete the parallelogram of forces FGHI, and draw its diagonal IF. Produce the line IH if necessary, to meet AC or CB in K, and draw KL perpendicular to GI. Then will IL, which forms a part of the first parallelogram of force, represent the resistance which the body receives in the direction BA; and LI, forming a part of the other parallelogram of force, denote the effort of the fluid on the hinder part of the body, and which contributes to help it forward in the direction in which it moves.

Let the form of the entire body be limited to the condition that CM is perpendicular to AB, and that the latter diagonal is bisected by the former. Assume FG $= m$, and FH $= n$; and let the areas of the planes CE, CP, and CN be respectively denoted by A, B, and C.

By similar triangles we have,

$$KH = n \cdot \frac{DC}{AC},$$

$$\text{whence } IK = n \cdot \frac{DC}{AC} + m,$$

and $IL = \frac{DC}{AC}\left(n \cdot \frac{DC}{AC} + m\right)$ which is the measure of the resistance at the point F, produced by the forces FG and FH.

But the number of pressures represented by FG, is to the number represented by FH as the areas A and C. Consequently the effect of the water on the fore part of the body will be

$$A \cdot m \frac{DC}{AC} + C \cdot n \cdot \frac{DC^2}{AC^2}.$$

And, by a similar mode of reasoning, we obtain for the effect of the water on the after part of the body, the function

$$B \cdot m \cdot \frac{DC}{BC} - C \cdot n \cdot \frac{DC^2}{BC^2}.$$

If now we subtract the latter of these expressions from the former, we shall obtain for the resistance of the body, in the direction AB, the function

$$A \cdot m \cdot \frac{DC}{AC} + C \cdot n \cdot \frac{DC^2}{AC^2} - B \cdot m \cdot \frac{DC}{BC} + C \cdot n \cdot \frac{DC^2}{BC^2}.$$

But since A : AC :: B : BC, therefore $\frac{A}{AC} = \frac{B}{BC}$; or by multiplying each side of the equation by m . DC, we shall farther have $A \cdot m \cdot \frac{DC}{AC} = B \cdot m \cdot \frac{DC}{BC}$; and hence the preceding expression for the resistance is reduced to

$$C \cdot n \cdot \frac{DC^2}{AC^2} + C \cdot n \cdot \frac{DC^2}{BC^2}.$$

And from which we deduce, that so long as the velocity is not sufficient to produce an elevation of the water before, and a depression abaft the greatest breadth, so as to increase the fore resistance and diminish the aft, the body will experience the same resistance, whether the sharp or obtuse extremity moves forward; and yet that the resistance will be the least when the two extremities are equal, or when the greatest breadth is in the middle.

But, if we suppose that the water runs ahead of the ship before its greatest breadth, with a velocity represented by v, and that it has acquired a velocity w in a direction opposite to that of the body abaft this greatest breadth, then the velocity forward will be denoted by $n - v$, and the velocity aft, by $n + w$.

Since, moreover, the resistance is in proportion to the squares of the velocities,† the general expression for the resistance will be changed to

$$C \cdot (n - v)^2 \frac{DC^2}{AC^2} + C (n + w)^2 \frac{DC^2}{BC^2},$$

* Clairbois, in alluding to this observation of Chapman, remarks, that "this elevation of the water before the ship forms a kind of prow of water, whose figure is not so well adapted for dividing the fluid as that of the ship: and the ship being preceded by this prow of water, cannot overcome so easily the resistance of the fluid, as if it divided it immediately, which it does very nearly when the velocity is small."

† This hypothesis was afterwards modified by Chapman.

where we suppose C' to be greater than C, inasmuch as the water before the greatest breadth is more elevated than behind it.

Hence it is evident, that whatever relation exists between the elements n, v, and w, the body meets with less resistance when the obtuse end is forward, than when the acute end is so placed; and that the position of the main breadth with respect to the middle point of the body, depends on the quantities $n-v$ and $n+w$, in order that the resistance may be less than if its situation were anywhere else.

It is manifest also, that the greater v and w are with respect to n, the more the greatest breadth should be carried before the middle, in order to render the resistance the least.

No supposition can be imagined in which the elements n and v become identical; because in such a case, the water would flow forward with an equal velocity to the ship, a condition by no means admissible. It is also to be remarked, that v becomes very small with respect to n, when the velocity is small, and may even be supposed to vanish when n becomes very minute. The same thing also takes place with respect to the water abaft the greatest breadth, when the velocity is small, and the body has its maximum breadth very far aft, the water following the body to fill up the void space which it leaves. From this cause a part of the water follows the same direction as the body, the velocity of the body in relation to the water being $n-w$, and which therefore gives to the preceding expression for the resistance, the still more general form of

$$C'(n-v)^2 \frac{DC^2}{AC^2} + C(n+w)^2 \frac{DC^2}{BC^2}.$$

Such is the general expression for the resistance as given by Chapman,—an expression which it is proper to apprise our readers cannot be entirely depended on, inasmuch as he admits in it two suppositions, which have been repeatedly proved by experiment to be false. The first of these suppositions is, that the resistance to a plane surface varies as the square of the sine of the angle, which the surface makes with the line of motion; and secondly, when the angle is given that the resistance varies as the square of the velocity.

This general expression for the resistance is subject to different varieties of value, according to the relative dimensions of AC and BC; and there is moreover involved in its consideration, the position of the greatest breadth, when the resistance itself is a *minimum*, —a principle of great importance in the practice of shipbuilding. Dr. Inman, by reducing the expression for the resistance to a differential equation, has found, when the length is four times the breadth, that the greatest transverse section of a ship ought to be about $\frac{1}{72}$d of the length before the middle; or when the length is to the breadth as 3 to 1, about $\frac{1}{67}$th of the length before the same point.

Chapman deduces the conclusion, that to render the resistance always a minimum, the place of the greatest breadth ought to vary,—a condition obviously impossible.

In order, however, to put our readers in possession of the method employed by Chapman for estimating the resistance on a ship, we shall adopt his co-efficients of resistance, that for the forepart of the vessel being 6, and for the afterpart 7.* The expression for the resistance on the forepart of the vessel will therefore be

$6\,C \times \frac{DC^2}{AC^2}$, and on the after-part $7\,C \times \frac{DC^2}{BC^2}$. These expressions we shall now endeavour to apply.

Let ACDB, Fig. 1, Plate CCCCXCI. be a plane inclined at any angle to the horizon, and let the fluid impinge on it with a force represented by EF, in a horizontal direction from E to F.

From F, let FI be drawn parallel to the horizon, and from E, the line EG perpendicular to the assumed plane. Then will EG represent the measure of the force which acts at right angles to the plane. From G draw GH perpendicular to EF. Then will EH denote the relative action of the *direct force*. From E also, draw EI perpendicular to FI, and join the points G and I; then will the plane EGI be perpendicular to the horizon. Moreover, from G let a perpendicular be drawn to EI, or, which is the same thing, to the horizon, and then will GK represent the relative *vertical force*. Join the points K and H, and which being perpendicular to EF, will represent the relative *lateral force*. Hence the *relative direct*, *vertical*, and *lateral forces*, acting at the point F, are represented in value by the lines EH, GK, and KH.

To apply these principles to the fore-part *a c d* of a ship, Fig. 2, let *a a*, *b b*, *c c*, &c. represent some of its water lines, at equal distances from each other; and AK, BL, MN, &c. vertical sections, also at equal distances from each other. The intersections of these water lines and vertical sections, will form a series of trapeziums, each of which must be divided into triangles, by having its diagonal drawn. Draw, for example, the diagonal AD of the trapezium ABCD; and from D and A the extremities of the same diagonal, draw the lines DF and AE perpendicular to AC and DB; and from E and F, in like manner, let fall the perpendiculars EH and FG to the water lines *a a* and *b b*.

In the next place, in Fig. 3, draw the parallel lines RS and PQ at the same distance from each other, as the vertical sections, and to these lines draw the perpendicular RP. Transfer the distance DF in Fig. 2, from P to T in Fig. 3. Draw TR, and from T draw TU perpendicular to TR, to meet RP produced in U.

If, now, UR be supposed to express the absolute force of the fluid, UP will represent its relative *direct* action; FG, Fig. 2, its *vertical* action, and GD, in the same figure, its *lateral* action, those lines representing the fluid's action on the triangle ACD. Now, as the absolute force is constant, we may adopt for its representative the interval between the sections: and, for this purpose, draw PW at right angles to RT, and WX perpendicular to RP. Then will PX denote the relative *direct* force.

From Fig. 2, transfer the distance FG, which is the vertical force, when the absolute force is denoted by RU, from Z to Y in Fig. 3. And as the force RU has been reduced to RP, so the force, whose measure is ZY, should be reduced in the same ratio. Draw,

* It is proper to apprize our readers that these co-efficients of resistance are deduced from a particular supposition, one of the conditions of which is, that the velocity of the floating body is always the same.

therefore, the line TX; and since YZ : Qβ : : RP : RX :: RU : RP, it follows that Yβ will represent the relative *vertical* force on the triangle ACD.

Again, transfer DG from P to γ in Fig. 3, and draw γR. Then, in the same manner, will δX be the measure of the lateral force on the same triangle; and it will moreover appear, that RP being the measure of the absolute force, Px, βY, and δX will be the measures of the relative *direct*, the relative *vertical*, and the relative *lateral* forces; and we shall obtain the entire effect of these forces by multiplying each of them respectively by the triangular area ACD. In a similar manner may the effect of the fluid be ascertained on the triangle ADB, and on every other triangular area which may be found on the surface of the vessel.

If, therefore, the effect of the resistance on the forepart of the vessel be represented by M, and that on the afterpart by N, it follows that by applying the co-efficients of resistance, the whole resistance will be proportional to 6M + 7N. But as we have taken for the representative of the absolute force, the distance between the sections, and which may be greater in one place than in another, the relative force on one ship cannot be compared with that of another. It hence becomes necessary to find a plane figure, which, being moved in the water with the same velocity as the ship, shall meet with the same resistance. Such surface is called the *plane of resistance.* To determine the value of this plane of resistance, let x represent it, and let m be the absolute force of a particle. Then will mx be the resistance on the forepart of the vessel, and the same quantity mx be also the measure of the negative resistance, or the diminution of the pressure forward, in consequence of the motion. Hence, multiplying by the coefficients of resistance, we shall have $6mx + 7mx = 13mx$, for the measure of the whole resistance on the plane represented by x; that is $13mx = 6M + 7N$, and $x = \frac{6M + 7N}{13m}$. If we suppose M = 18, N = 16, and $m = 5$, we shall have $x = 3.38$, that is, the ship will meet with the same resistance as a plane whose area is 3.38 feet, when moved with the same velocity as the ship.

To apply this investigation to the actual circumstances of a ship, let Fig. 4 be referred to, and which is supposed to represent the vertical plane of the body.

The equally distant sections are represented by π, β, Z, X, u, &c. afore the section ϕ, and by 32, 30, 28, &c. abaft the same plane. The line 1, 1, also, denotes the load water section, and below which are drawn the parallel and equally distant planes, 2, 2; 3, 3; 4, 4, &c. By this construction, the whole surface of the body becomes divided into trapeziums, like B$\pi\beta$E, each of which, by means of one of its diagonals as πE, may again be divided into triangles.

From A, in the same figure, draw AC perpendicular to Bπ; and from π and E, the lines πI and EF, perpendicular to Eβ and Bπ. Again from C, draw CD perpendicular to the water line; and from F and I, the lines FH and IG also perpendicular to the same line; and in this manner proceed for all the triangular spaces.

This being accomplished, draw, as in Fig. 1, Plate CCCCXCII, two parallel lines IK, LM, at the same distance from each other, as the sections, and draw NO at right angles to them. Set off AC, Fig. 4, Plate CCCCXCI, from N to P in Fig. 1, Plate CCCCXCII, and make NQ equal to the distance of the section π from the stem, and draw PQ. But as the interval between the first section π and the stem is less than that between the sections, and as this latter distance is taken for the perpendicular effect on the forces on every space, draw from the point O, the line OR parallel to PQ.

Set off also DC, Fig. 4, from U to W in Fig. 1, Plate CCCCXCII, perpendicular to NR; and from N, draw through the point W, the line NX. Also from N, let fall the perpendicular NS on OR, and from S, the perpendicular ST upon NO. Then it will follow from the preceding investigation, that NT will be the relative *direct* force acting on the surface of the triangle ABπ.

Again, draw RT, and from X, the right line XY perpendicular to LM. Then will XY be the *vertical* force which acts against the same triangle; and in this manner are found the *direct* and *vertical* forces acting on the triangle 25, Fig. 4.

To find the direct and vertical forces which act on the triangle 24, we make ab, Fig. 1, Plate CCCCXCII, perpendicular to LM, and set off the distances EF, Fig. 4, Plate CCCCXCI, from a to c, Fig. 1, Plate CCCCXCII. From a draw also ad perpendicular to bc, and from d, the line de perpendicular to ab. Then will ae be the *direct* force. Draw again ce, and set off the distance FH, Fig. 4, Plate CCCCXCI, from the line bc, Fig. 1, Plate CCCCXCII, to the line LM perpendicular to the latter. Then will fg represent the vertical force acting on the triangle 24, Fig. 4, Plate CCCCXCI.

These various forces, multiplyed by the areas of the respective triangles, will produce the effect of the fluid on each of them.

In the same manner may the forces on the afterpart of the vessel be found, the construction for which is represented in Fig. 2, Plate CCCCXCII.

The distance between the sections is 4.95 feet; and between the water lines 2.25 feet. The computations for the direct forces, are entered in the following Tables:

Recapitulation of the direct Resistances between the Lines of Flotation.

For the part afore ∅.		For the part abaft ∅.	
Between the 1st and 2d water-lines - - - - - - =	36.48	Between the 1st and 2d water-lines - - - - - - =	23.91
2d and 3d =	25.34	2d and 3d =	15.04
3d and 4th =	15.89	3d and 4th =	9.05
4th and 5th =	9.47	4th and 5th =	5.34
5th and 6th =	3.93	5th and 6th =	2.46
6th and 7th =	0.95	6th and 7th =	0.59
Against the Stem =	13.16	Against the Rudder =	20.00
Whole resistance afore ∅ =	105.22	Whole resistance abaft ∅ =	76.39

The formula representing the value of the plane of resistance, was before found to be $\frac{6M + 7N}{13m}$. And in the example before us, the value of $M = 105.22$; of $N = 76.39$, and of $m = 4.95$. Hence the numerical value of the half area of the plane of resistance.

$$= \frac{6 \times 105.22 + 7 \times 76.39}{13 \times 4.95} = 18.12.$$

Consequently, the vessel whose resistance we have endeavoured to estimate, will experience a resistance equivalent to that of a plane whose surface is 36.24 square feet; or, in other words, of a square whose linear edge is 6 feet, the velocity of the plane being the same as that of the vessel.

Such, however, are the difficulties attendant on this subject, that Dr. Inman, in a note to his *Translation* of Chapman's *Treatise on Shipbuilding*, observes that it is difficult to draw from the theory of resistances, "any particular conclusions applicable to shipbuilding," but that, "generally, the resistance to ships moving with the *same velocity*, seems to depend on the following circumstances:

First, on the area of the midship section, as causing a greater or less displacement of fluid by the motion of the ship.

Secondly, on the form of the fore body, as causing more or less additional resistance from the motion of the ship, considering only the inertia of the particles displaced;—that is, supposing the void space left astern in consequence of the displacement to be instantly filled by the fluid.

Thirdly, on the form of the after body, as causing a greater or less diminution of pressure forward, on account of the motion of the ship alone.

Fourthly, on the shape of the whole body, as affording a more or less easy and rapid transit of the displaced fluid to the stern; that is, to the void space, which otherwise would be left behind for an instant.

Fifthly, on the form of the whole body, with respect to direction and the quantity of superficies, as causing more or less friction, and more or less adhesion of the fluid."

In the construction of a ship, the displacement, Dr. Inman continues, is supposed to be a given quantity. The area of the midship section may be varied to a certain extent, and still the same displacement retained. The less this is, the less will be the resistance, since the quantity of fluid displaced in a given time will thereby be diminished; and this section will be the least possible (supposing the length given,) when the fore and after bodies are full, and every transverse section equal. But such a form, on many accounts, and even from the consideration of the resistance alone, could not be adopted. The impact of the fore body against the fluid would be too direct, the motion of the after body from the fluid would also be too direct, and the fluid displaced could not flow easily to the after parts of the ship.

Supposing the length of the ship to be undetermined, in that case, by increasing the length, the midship section might be diminished without limit. The body might at the same time be properly formed for cleaving the fluid, and also transmitting it to the stern. But then (without entering into any other consideration except the resistance,) the friction would be so far increased by the extension of the body, as to retard the ship more than if it were shorter, and the midship section greater. It appears, therefore, that the midship section cannot be too far diminished either by filling the fore and after bodies, or by extending the whole or either of these bodies without an increase of the resistance.

If the proper area of the midship section be supposed to be determined, it becomes a question in a general view, how the fore and after bodies must be formed so that the ship may meet with the least resistance.

The fore body, Dr. Inman continues, must be formed not only so as to cleave the fluid with the greatest facility, but also so as to disperse it to the right and left, and thereby facilitate its transit to the stern; at the same time it must diminish the resistance in one point of view, to form the after body, so that the two streams, which may be conceived to flow on the sides of the ship, may at the stern take as much as possible the same direction, namely, the one opposite to the direction in which the ship is moving. With these two views, therefore, the half of the ship before the middle must be filled a little more than the after part. Now this may be done two ways; either by carrying the greater transverse section before the middle, or by filling the whole fore body of the ship, and keeping the greatest section in the middle. But the superiority of the former method appears from the consideration, that by this means the proper effect is produced on the fore body, whilst at the same time a finer run may be given to the after body. Whence is seen the propriety of placing the greatest transverse section of a ship before the middle.

Upon the whole, therefore, in constructing a ship from a given displacement for fast sailing, we must give a proper area to the midship section, and also carry that section something before the middle. Care must be taken to shape the fore and after bodies,—the former, so that the fluid may be separated with facility, and at the same time the displaced fluid dispersed, and transmitted towards the centre; and the latter, so that the fluid displaced may flow with as great facility as possible to the stern. At the same time, the after body must not be elongated so as to increase the friction.

These general remarks have been made without any reference to the amount of the acting power, that is, the quantity of sail, which, however, it is very important to attend to in a construction. Supposing a ship to be formed with a given displacement, so as with a certain motive power (not producing inclination,) to sail the fastest, still it does not follow that its form is the best for moving through the water by means of sails, the power of which is exerted in inclining the ship, as well as in forcing it ahead. If this form were modified a little, so that a greater quantity of sail could be carried, without inclining the ship too far upon a wind, the increase of which sail would more than counterbalance the addition thereby caused in the resistance, the ship would be improved by this alteration in its quality of sailing. This consideration, therefore, must be added to those already adverted to, in constructing a ship for fast sailing.

We have anticipated in some measure a few observations, that would more properly have fallen under the head of Construction; but we were anxious to furnish our readers with the remarks of the distinguished Professor of the College of Naval Architecture, on Chapman's views relative to the resistance of fluids, in order to place every step of so difficult and mysterious a subject, in a candid and explicit point of view.

It may not be amiss, however, to allude more particularly to the experiments with which Mr. Chapman says his formula of resistance $C' \times \frac{DC^2}{AC^2}\left(n - v\right)^2 + C \times \frac{DC^2}{BC^2}\left(n + w\right)^2$ is found to agree.

In a large and deep pond, says he, were placed a hundred feet from each other, two poles A, B, and two piles C, D, Fig. 5, Plate CCCCXCI. to which were fitted two copper pullies, and through these were reeved ropes to support the weights, as represented in the figure. The lines E and G were attached to the body employed in the experiment. On the line E, a weight was placed, to give motion to the body in the water; and on the other line G, there was also a weight, but less than the first, to keep the body in the straight line from which it would have deviated without it. To the line E were tied two small pieces of red cloth I, K, at the distance of 74 feet from each other. To measure the time, a stop watch showing seconds was used. When the mark arrived at L, the stop watch was let go, and when the mark I was come to the same point, the watch was stopped. It then showed the number of seconds which the body F took up to pass over the space of 74 feet. The bodies with which the experiments were performed, were of wood, and 28 inches in length. The transverse sections under the water were circular. Their diameters at the greatest breadth were $\frac{2}{7}$ of the length, or 8 inches, and the water lines either straight or conic parabolas, and the vertex of the parabolic curve was at the greatest breadth. As the bodies were lighter than water, lead was run in, until their specific gravity was nearly equal to that of sea water, so that they only just floated, having their axes parallel to the surface of the water. The weight attached to the line E, to put the body in motion, was varied according as it was required to increase or diminish the velocity; but the retarding weight was always the same. The bodies employed were the following:

Fig. 6, Plate CCCCXCI. having its greatest breadth at the middle, and its extremities formed by parabolic lines.

Fig. 7, ——— having its greatest breadth at $\frac{2}{7}$ of its length from the point B. The extremities also were parabolas.

Fig. 8, ——— having its greatest breadth at $\frac{1}{7}$ of the length from the point D, the extremities still parabolic.

Fig. 9, ——— having its greatest breadth at the middle. The extremity F parabolic, and the other G conic.

Fig. 10, ——— having its greatest breadth at $\frac{2}{7}$ of the length from the point H. The extremity H parabolic, the other conic.

Fig. 11, ——— having its greatest breadth at $\frac{2}{7}$ of the length from the point O. The extremities conical.

Fig. 12, ——— wholly conic, having its greatest breadth equal to that of the other bodies, and its length twice and a half the breadth.

The results of the experiments performed with these bodies, are recorded in the following table:

		Fig. 6.	Fig. 7.		Fig. 8.		Fig. 9.		Fig. 10.		Fig. 11.		Fig. 12.

To understand the nature of these experiments, let the example of Fig. 7 be selected, in which the *moving* weight was equal to that of the entire body; and the *retarding* weight, half the same quantity. It may then be remarked, that with the extremity B forward, the body will pass over 74 feet in 14 seconds; but with the sharper end C in a similar situation, the body will pass over the same in $14\frac{1}{2}$ seconds. In like manner, with the body represented in Fig. 10, and the same conditions of the moving and retarding weights, when the parabolic extremity of the body was moved forward, the time of describing 74 feet was 15 seconds; but with the conical extremity under the same circumstances, the same space was described in 16 seconds.

Each of the experiments recorded in the table, Chapman informs us, was repeated six times, with considerable uniformity. The velocities, he remarks, do not present the proportionality we might be led to expect from a consideration of the weights,—a circumstance, however, which he attributes to a division of the fluid too near the surface. The number of pullies over which the line passed, rendered the experiments less exact, on account of friction. The friction, however, being the same for all the experiments, the variation in the velocity ought to be the same.

The inferences Mr. Chapman draws from his experiments are the following: First, *That when the motion is slow, the body has a greater velocity when the sharper end is forward, than the full.* Secondly, *That when the velocity is increased to a certain degree, the body passes over the same space in equal times with either extremity forward.* Thirdly, *That when the velocity becomes still greater, the body takes a less time to pass over the same distance when its obtuse end is forward. Thus, says he, it is the velocity of the body which should determine the place of the greatest breadth, to render the resistance* *the least*—a conclusion, however, we would add, that implies the inadmissible supposition of a variable position of the greatest breadth.

In the present state of our information respecting the important question of the resistance of fluids, we must receive almost every principle deduced from it, with the greatest circumspection and caution. We regret, as we have before remarked, our inability to furnish any satisfactory information on the subject; but we should only have misled our readers had we not honestly confessed the state of our knowledge on this great question. We might have enlarged very much, it is true, this part of our article, by some elaborate theoretical investigations, and perhaps have shown their coincidence with *certain particular experiments.* But no real and solid information would have been gained from trains of analytical investigation, which, at the moment of their *practical* application to naval architecture, seem almost, as Mr. Harvey expresses it, "to lose their identity," leaving nothing behind but the regret, that so much labour and earnest zeal should have produced so little that is useful to man, for the purposes of shipbuilding.

We regret, however, that our limits will only merely allow us to allude to the experiments performed at the Greenland dock, in the years 1793, 1794, 1795, 1796, 1797, and 1798, by a Society instituted expressly for the noble and patriotic purpose of improving naval architecture. These experiments amounted to nearly 10,000 in number, and were published under the auspices of the Society in a thin quarto volume, now become very rare. The labour must have been immense; and we gladly record our warm admiration of the industry and zeal that animated the members of this most useful Society. In the introduction to this article, we alluded to the advantages that would result from the establishment of a Society expressly devoted to the cultivation of naval architecture, both in theory and practice. We yet hope to see this accomplished; and we are sure that whenever that great object may be accomplished, its founders will not overlook the labours of the ingenious members of the Society above alluded to.

ON THE SAILS OF SHIPS.

The principal object in the formation of a ship, is its motion through the water, and the action of the wind on the sails is the great source from which that motion is derived. The degree in which this action is exerted, is dependent in a great measure on the size of the sails, and therefore the right determination of their forms and dimensions, is a subject of much importance to naval architecture.

To obtain as great a degree of velocity as possible, the dimensions of sails are sometimes carried beyond those limits which the safety and stability of a vessel sanction; but there must be some proportions and sizes for sails, which shall ensure to every class of ships, the *maximum* conditions of the very important elements of stability and velocity. This, however, is one of the many important elements yet to be determined by the future cultivators of naval architecture.

Let us in the first place attend to a few simple considerations connected with this very important subject. Suppose, in the first place, the line AB, Fig. 3, Plate CCCCXCII. to represent the water section of a vessel; and, in it, let DG be assumed as the measure of the fluid's horizontal action against the head of the ship; and since from the assumed theory of resistances it is known, that when a ship is in motion, the action of the water on the after part of the vessel is distinguished by a sign opposite to that which characterizes the fluid's action on the bow; let IE in the same horizontal line be assumed as the measure of its action, and in its proper numerical relation to DG. Let GH, also at right angles to the water section, denote the vertical force of the water upon the head, the direction of which is from G to H; and KI the direction of a similar force acting on the after part, the direction of which is from K to I. Join DH, which will be the resultant of the first pair of forces acting in the direction DH. Join also KE, which will be the resultant of the second pair of forces, and the action of which will be exerted from K to E.

Produce these resultant forces to meet in F, and make FN and FO respectively equal to them; and let these forces, in their new condition, be supposed to change their character from resultant to component forces, and complete the parallelogram FNPO, and draw its diagonal PF, and let it also be produced to Q. From the centre of gravity C of the ship, let fall CL, CM, and CQ perpendicular respectively to DH, EK, and PF. Then by a well-known theorem in mechanics, we have the following equation:

$$FN.\ CL + FO.\ CM = FP.\ CQ;$$

and if, therefore, PF denote the force and direction of wind, and the centre of gravity of the sails be in the line PF, the surface of the sails being perpendicular to the same line, the ship, as a necessary consequence, will be impelled through the water by the action of the wind, without having either of her extremities elevated or depressed.

Now this line PF which represents the direction of the wind's action, is *inclined* to the water's surface; whereas its direct action may be supposed more generally to operate in a *horizontal* direction; and therefore from the points C and N let CW and NS be drawn perpendicular to the horizon, and from the point F, the line FR parallel to the same plane. Through P also, draw TR parallel to NS.

This construction furnishes the similar and equal triangles DGH, FSN, and EIK, NTP; and from which we have DG = FS, and EI = NT or SR. Hence FS + NT = DG + IE = FR, the measure of the entire direct resistances.

The triangles CQW and FRP being similar, we have also the proportion

$$CQ : CW :: FR : FP$$

and from which we obtain

$$CQ \cdot FP = CW \cdot FR$$

Hence the equation derived from the well-known theorem in mechanics before given, becomes

$$FN.\ CL + FO.\ CM = CW.\ FR;$$

so that the horizontal effort of the wind on the sails, being necessarily equal to the horizontal effort of the water on the hull of the vessel, the point W will be the proper height of the centre of gravity of the sails, now that the direction XY of the wind has been assumed parallel to the horizon.

These conditions, if it were possible rigidly to maintain them, would preserve both extremities of the vessel from being either elevated or depressed. But there are circumstances continually operating, to destroy this uniformity of condition; sometimes tending in their consequences to elevate the centre of gravity of the sails above the point W, and at other times to depress it. If the former condition take place, and the centre of gravity of the sails be supposed at α, the effect will be to depress the bow of the vessel; but if, on the contrary, the centre of gravity be situated at β, below the centre of gravity W, before determined, the effect of the wind will be to depress the stern. In order, therefore, that the sails may have no tendency to produce either an elevation or depression of the stem or the stern, the centre of effort of the wind on them, should be situated somewhere in the line XY.

Hence we may perceive of what importance it is to have a right determination of this centre. For if we suppose it situated at either α or β, an increase of sail would not increase the velocity of sailing in proportion to the surface, since one or other of the extremities must, under such circumstances, be depressed, and consequently, the resistance increased.

Mr. Chapman truly observes, that in a ship full at the load water line forward, and lean below, the resultant of the effort of the water rises very much; and therefore, in order for it to sail well, it ought to have high sails. But in a vessel whose forepart is full under the water, the resultant will not rise so considerably; and, consequently, to possess proper qualities of sailing, it ought to have its sails of a less elevation. The after part of a vessel is equally to be considered with its fore part in determining the centre of effort of the sails. The latter condition, however, is too often lost sight of in inquiries of this kind.

Hence also it may be observed, that two ships of the same length, breadth, and tonnage, may possess equal stability, and yet require different heights of tho sails to move equally well with the wind aft.

To determine, says Mr. Chapman, the necessary surface for sails, it would be necessary to enter into many long and laborious calculations, and which, in the end, would produce no result of great practical importance. A better plan is to compare plans of different ships whose properties are known, and to draw from the comparison, such results as will enable us to ascertain the proper and necessary relations of the centre of effort of the wind on the sails, and the stability.

Let, for example, ABC, Fig. 4, be a vessel inclined by the effort of the wind HG, and let AB be the load water line, D the centre of gravity of the ship, E the centre of gravity of the displacement, and G the centre of effort of the wind on the sails. If now, from E, we draw a vertical line EF, the point F will be the metacentre. Moreover, from D, draw DK perpendicular to EF, and let the force of the wind, which acts perpendicularly to the line GD, be represented by U, and that which acts in the vertical line EF, and which is equivalent to the displacement, by D.

Now, as the motion of rotation is performed round the centre of gravity, the moment of the sails to incline the ship will be equivalent to GD . U; and the moment of the ship at the same time, to resist the inclination DK . D. But since, whatever be the magnitude of the interval between the metacentre and the centre of gravity of the vessel, it preserves a constant relation to KD at equal inclinations, the moment of the ship to resist inclination may always be expressed by FD . D, and which moment ought to bear a certain relation to the moment of the sails DG . U, in order that the degree of inclination may be the same.

The wind acting, moreover, in the direction HG, the ship will be impelled from B towards A, the resistance of the water acting in the line IL, which therefore passes either above or below the centre D. If this line passes above the centre of gravity D, the stability will be increased, and if below it, the stability will be diminished.

Very great labour is necessary, in order to calculate for any ship, the line in which the resistance of the water operates on the side; and Mr. Chapman remarks, that it is sufficient to know that the mean direction of this resistance rises less is ships, the hulls of which are very lean towards their extremities and keels, than in those ships which possess a fulness throughout. The effect on the stability, Mr. Chapman observes, cannot be considerable, if we suppose this mean direction to pass through the centre of gravity of the ship; and hence the moment of the sails relatively to this last mentioned point, should always bear a certain relation to the whole weight of the ship, multiplied by the distance of its centre of gravity D from its metacentre F; that is to say, the moment of the sails in all the ships is equivalent to m . D . DF, in which the co-efficient m must be determined by experiment.

Mr. Chapman remarks, that by calculating the moment of the sails for several ships, he has found the value of $m = \frac{35.5}{x^{\frac{1}{3}}}$, where x denotes the length of the ship from the stem to the stern post; and hence the preceding formula for the moment of the sails is $\frac{35.5}{x^{\frac{1}{3}}}$. DF . D.*

But the most remarkable anomalies are presented by merchant ships in this particular department of naval architecture; anomalies which owe their origin to the different specific gravities of their cargoes; and producing different elevations or depressions of the centre of gravity, with the same constant draught of water. And hence also it follows, that ships in different voyages, having cargoes of different specific gravities, must present different varieties of values for their moments of stability, and consequently equally varied results in the efforts of their sails.

To determine the position of the centre of gravity of the sails, both as regards its elevation above the plane of the load water section, and its position with respect to the length of the vessel, recourse must be had to the method of moments, before applied in determining the centre of gravity of the ship. This method we illustrated by the general formula

$$\frac{p\,x + p'\,x' + p''\,x'' + \&c. - (x\,\pi + \pi'\,x' + \pi''\,x'' + \&c.)}{p + p' + p'' + \&c. + \pi + \pi' + \pi'' + \&c.};$$

and in applying it to the determination of the altitude of the centre of gravity above the load water section, it is manifest that the elements denoted by the consecutive values of π and x will vanish, because all the moments are situated on the *same* side of the plane to which their effects are to be referred; but in applying it to the determination of the position of the same point with respect to the length of the vessel, one term $\pi\,x$ will preserve its negative character, in consequence of the centre of gravity of the spanker sail being situated abaft the assumed vertical line $x\,y$, Plate CCCCXCIII. which passes through the section (1),

* Dr. Inman has remarked that F is not truly the position of the metacentre when the inclination of the vessel is finite, and that the expression of the moment of the sails, given in the text, should be used with caution, especially in determining the proper quantity of sails for ships whose forms differ much from those adopted by Chapman as the basis of his investigation.

Plate CCCCLXXXVIII. Fig. 1. The formula, in the first case, will therefore be reduced to the form of

$$\frac{p\,x + p'\,x' + p''\,x'' + \&c.}{p + p' + p'' + \&c.}$$

and, in the latter, to

$$\frac{p\,x + p'\,x' + p''\,x'' + \&c. - \pi\,x}{p + p' + p'' + \&c. + \pi}.$$

To apply these formulæ to the purpose intended, recourse must be again had to Plate CCCCXCIII. which represents a draught of the masts, sails, &c. in their proper proportions. The first process of calculation is to determine the area of each sail by the ordinary rules of mensuration, and the position of the centre of gravity of each sail, by such graphical rules as the familiar writers on mechanics teach; and then estimating the distance of each centre from the planes to which their effects are intended to be referred. Thus, the area of the main-top-sail ABCD, and the position of its centre of gravity E, are found by applying the methods referred to, to the dotted lines contained in it; and then determining, first the distance EG of this centre from the load water line, and afterwards the distance of the same point EF from the assumed vertical plane $x\,y$. The results of the calculations of the areas of the several sails are recorded in the second column of the following table; the distances of their centres of gravity from the plane of the load water section in the third column, and the distances of the same points from the assumed vertical plane $x\,y$, are moreover entered in the fourth column. The multiplication of these areas by the proper distances of their centres from the assumed planes, will give the moments recorded in the fifth and last columns.

Hence the value of the last formula but one, will become, under the present conditions,

$$\frac{p\,x + p'\,x' + p''\,x'' + \&c.}{p + p' + p'' + \&c.} = \frac{1960570.49}{24511.83} = 79.98 \text{ feet},$$

which is the elevation (+)P of the common centre of gravity of all the sails, above the plane of the load water section.

And for a similar reason, the other formula produces

$$\frac{p\,x + p'\,x' + p''\,x'' + \&c. - \pi\,x}{p + p' + p'' + \&c. + \pi} =$$

$$\frac{2215546.163 - 20669.79}{24511.83} = 89.54 \text{ feet},$$

which is the distance (+) Q of the centre of gravity of the sails, before the assumed section $x\,y$.

Such is the method by which the position of the centre of gravity of the sails is determined.

In order, however, to determine whether the quantum of sail thus assumed, be that which the circumstances of the vessel require, a condition of equality must exist, between the aggregate of the moments thus determined, and the numerical product arising from the multiplication of the whole weight of the ship, by the distance of its centre of gravity from the metacentre.

If such an equality should not exist, the draught must be altered, until the desired relation be obtained; but here a wide latitude is open to the constructer, to correct the error that may exist. If, for example, the sails, according to their first disposition, should all bear a proper relation to each other, as far as *magnitude* is concerned, the alteration that the anomaly to be corrected may require, should affect them *all proportionally*. If, on the contrary, a partial alteration in the canvass will produce the correction desired, such an alteration should be applied, as will correct the defect. It is manifest, also, that any alteration in the surfaces of the sails will not only affect their areas, but also sensibly influence the positions of their centres of gravity, and thereby the general moment of the sails. Sometimes we fear alterations are made in sails, without a due attention to this important particular. But it should ever be remembered, that any new arrangement in the parts of a system, will in all cases affect the position of the centre of gravity of that system, and sometimes produce important effects on the general system with which those parts may be connected.

Suppose again it should be found that the elevation of the centre of gravity of the sails, above the plane of the load water line, is either too great or too small, but that its position with respect to the vertical section is correct, considerable judgment will be necessary, in any alteration of the sails, to preserve the centre in the same vertical line, and to give to it the elevation desired. On the other hand, the altitude of the same centre above the plane of the load water section, may be just that which a sound experience sanctions, but, that from some circumstances connected with the sailing quality of the

* This moment is distinguiseed by a negative sign, as already remarked, because the sail whose effect it is designed to indicate, is not on the *same* side of the assumed section (1), as the other sails.

vessel, it is desirable to remove it nearer towards the stern, or to cause it to advance towards the bow; in such a case equal judgment will be necessary in effecting any change. Sometimes, no doubt, in correcting errors of this kind, the attempt to remove one bad quality, is followed by the introduction of another; but in this, as in all human pursuits, the point to be obtained, is that which shall give the aggregate of the errors, of the least possible degree. Frequently, we believe, that canvass is added to sails, and their surfaces diminished with few considerations respecting their centres of gravity, or the laws of their momentum. Blind experience, unaided by the light of science, has too often been the guide of the mariner.

Chapman has given an admirable example to illustrate whether the common centre of gravity of the sails is well placed in regard to the mean direction of the resistance of the water, in a case wherein that centre is placed 67.22 feet above the load water line, and nearly $\frac{1}{10}$th of the length of the stem to the sternpost before the centre of gravity of the ship, but to which we can do no more than refer the reader, to Dr. Inman's translation of that important work.

The subject of the sails of ships is yet in its infancy, and well merits the attention of the man of science. Is it not remarkable, it may be asked, how few of our British mathematicians have directed their attention to matters connected with naval pursuits? The great problem of the longitude, and many other branches of nautical astronomy, have undoubtedly been wonderfully improved by their exertions; but the subject of shipbuilding has never in any considerable degree engaged their attention. The great end and object of science, is to turn its chief course towards objects of public utility; and now that we see the paths of discovery opening before us, in this most noble and interesting pursuit; "we must follow boldly wherever they lead us; confident that, sooner or later, theoretical knowledge must eventually contribute to the benefit of society, with regard to the more practical purposes of life."

ON THE DIMENSIONS AND DIFFERENT FORMS OF SHIPS.

One of the first and most important considerations which a naval constructer has to attend to, is the relation which the co-ordinate dimensions of a ship bear to each other;—how the length should be related to the breadth, and how both these elements are connected with the depth. *Duhamel*, in his *Architecture Navale*, has made it the subject of a particular examination, but we shall prefer following *Chapman* in his important remarks on this subject.

This able writer enters on the investigation, by supposing two bodies of different forms, one being that of a rhomboid, of which the uppermost surface is taken for the load water line, as Fig. 5, Plate CCCCXCII. and the other that of a body formed by the junction of two wedges ABGE, CGED, as Fig. 6, and whose upper surface, the rectangle ABCD, is, in like manner, taken for the load water section.

Suppose these bodies to be impelled through the water by a quantity of sail proportional to their stability; and let their half lengths moreover be represented by L, their half baeadths by B, and their draught of water by D. The moment of stability for the first of these bodies will be $\frac{B^3 \times L}{4}$, and the plane of resistance $\frac{B^3 \times D}{L^2 + B^2}$. A body of such a figure, however, could not acquire a great velocity by means of sails, and would sail badly close to the wind.

The moment of stability of the second body will be $B^3 L$, and the plane of resistance $\frac{D^3 B}{L^2 + D^2}$. And since the moment of stability increases in a triplicate ratio of the breadth, whilst the plane of resistance increases only in the simple proportion of the same dimension, this form is the best adapted for sailing close to the wind. This body also being impelled through the water, the square of its velocity will be in the direct ratio of the area of the sails, and in the inverse ratio of the plane of resistance. But the moment of stability is as that of the sails; and the moment of the sails, as the area of the sails multiplied by the height of a certain point, and which altitude is also proportional to the height of the sails; consequently, the area of the sails is, as the moment of stability, raised to the power of $\frac{2}{3}$, that is to say, as $(B^3 L)^{\frac{2}{3}}$. The area of the sails, therefore, divided by the plane of resistance $= \frac{(B^3 L)^{\frac{2}{3}}}{B \times D^3} (L^2 + D^2) = B \left(\frac{L^{\frac{8}{3}}}{D^3} + \frac{L^{\frac{2}{3}}}{D}\right)$; and hence the velocity will be as $B^{\frac{1}{2}} \left(\frac{L^{\frac{4}{3}}}{D^{\frac{3}{2}}} + \frac{L^{\frac{1}{3}}}{D^{\frac{1}{2}}}\right)$. But since $L^{\frac{1}{3}}$ is very small when compared with $L^{\frac{4}{3}}$, we may neglect the last term of the expression, and regard the velocity as proportional to $\frac{B^{\frac{1}{2}} \times L^{\frac{4}{3}}}{D^{\frac{3}{2}}}$*

From this expression for the velocity, Chapman draws some useful practical inferences. In the first place, that when the area of the load water surface is given, a ship to sail well by the wind should have great length according to its breadth, and the draught of water the smallest possible. If, however, the area of the load water section be not given, but only the length of the vessel, it will be necessary to give very great breadth, because the velocity increases as the square root of that dimension. But if the breadth be given, the length should be considerable, because this dimension is raised to the $\frac{4}{3}$rd power, when the draught of water is given. If, on the other hand, from a certain determined length or breadth, we have the choice of augmenting one of these dimensions, it is most advantageous, if the object be to increase the velocity, to augment the length rather than the breadth. And from all these considerations, Chapman infers that there cannot be any constant proportion assigned between the length, the breadth, and the draught of water.

* Let F = force of the wind on the sails, S = surface of the sails, A = area of the plane of resistance, R = resistance, and V = velocity. Then $R \propto AV^2$; but $R = F$, and $F \propto S$. Consequently $S \propto AV^2$, and $V^2 \propto \frac{S}{A}$.

Let H also be the height of the point of the sail, then the area of the sails, $\times H \propto$ stability; or since $H \propto S^{\frac{1}{2}}$; therefore $S \times S \propto^{\frac{1}{2}}$ stability. Consequently $S \propto (\text{stability})^{\frac{2}{3}}$.

From these circumstances also we may derive some information why a small ship, built on what is technically called the model of a large ship, known to possess very desirable qualities, should be found to have no properties analogous to the vessel from which she was deduced. This will be apparent, by attending for a moment to the elements of the expression for the velocity, all of which by the supposition are variable, but as they are constituted in the formula, vary by different laws. Suppose velocity to be the standard of comparison, and that its value in some determinate case be denoted by 10; that is,

$$\text{suppose } \frac{B^{\frac{1}{2}} \times L^{\frac{4}{3}}}{D^{\frac{3}{2}}} = 10;$$

the question is, what ought to be the other dimensions of a vessel, whose length is previously fixed at l, to possess an equal degree of velocity with that which is given? To this interesting and important question, no satisfactory answer, we fear, can be afforded in the present state of our knowledge. There is no doubt *some* relation existing between these primary dimensions in ships of different classes; so that having the length, the breadth, and draught of water of a ship of one class given, with a certain numerical velocity, the same velocity might be obtained, with dimensions suited to a ship of another class. Such a relation, and even we fear the feeblest beginnings towards it, can hardly be made the subject of calculation; but it is, however, a condition, to the attainment of which all our efforts will, we hope, continually tend. Had Euler, for example, been as well acquainted with the Philosophy of Naval Architecture, as with those beautiful systems of analysis, which it was ever the object of his sublime and original genius to create and improve, some approximations towards these relations would, no doubt, have been attained. Let us hope that the future cultivators of Naval Architecture will unceasingly endeavour to attain these things.*

The qualities of similar ships varies, Mr. Chapman imagines, in a different proportion from what a consideration of their size would give.

To illustrate this, he remarks that if the breadth of a vessel be regarded as variable, the burthen of the ship will vary as the cube of that dimension, and the velocity of sailing as the cube root of the same. The number of the crew also, which is proportional to the area of the sails $B^2 L^{\frac{2}{3}}$, will vary as $B^{\frac{8}{3}}$. Hence, by supposing two ships, whose capacities for burthen are in the ratio of eight to one, and their relative velocities as ten to eight; if the larger vessel sail with a crew of twenty-four men, the smaller will require four. According to the capacities of the two ships, the latter ought to be navigable by three men. Hence also we perceive, that in making small ships similar to large ones, the former will possess the worst sailing qualities, and will require a more numerous crew in proportion to their capacities than large ones.

Mr. Chapman also remarks it is possible to render a small ship navigable by a crew proportionate to its capacity; but that it cannot be done without diminishing the quantity of canvass, and then the sailing qualities of the vessel will be impaired. This fault may be remedied to a certain degree, by giving it less breadth; but this would be attended with inconvenience. Hence we prefer in small ships the property of sailing well, to having it in our power to diminish the crew.

The velocity also being in proportion to the quantity $\frac{B^{\frac{1}{2}} L^{\frac{4}{3}}}{D^{\frac{3}{2}}}$, increases as the depth decreases, supposing at the same time the length and breadth to increase. This object may be attained more easily by adding to the length, but for the greater safety of the navigation it is more convenient to increase the breadth. This will elevate the metacentre. The sails also may, in such a case, have an increased surface; but the ship would require a more numerous crew.

Great and small ships moreover cannot, with the same form, sail with the same security; nor can we avoid the inconvenience of being obliged to have a more numerous crew in small ships than in large. Small ships, therefore, cannot have the same advantages as large ones, when they are employed in the same trade.

As small ships lose in the quality of sailing, by being assimilated in form to large ones, so large vessels will improve this valuable property by being moulded similar to small ones. Mr. Chapman hence concludes, that it is proper to give to large ships forms similar to small ones, because they would thereby gain in the quality of sailing. But for merchant ships, where it is so much the more necessary to give great capacities in the water, as they are larger, they seldom want a superior quality of sailing, provided they are sufficiently stiff upon a wind not to be embayed on a lee shore. Added to this, in such a case, these ships would lose the advantage of sailing with a small crew, and as they cost more in construction in proportion than small ones, it is necessary in their formation to endeavour to combine qualities most advantageous to the interests of their owners.

In the following table is recorded the values of certain essential elements in shipbuilding, derived from one primitive element, the burthen, and which, owing its origin to Chapman, and deduced by him from a long course of experience, will be considered as very valuable.

* It was the object of Euler, in the valuable treatise he has bequeathed to us, to consider, from particular principles, certain conditions connected with the construction and properties of vessels. Had that great man been supplied with data to have entered on the *comparative properties* of vessels in general, what might we not have expected from his fertile and original mind? At the present moment this appears to us the great object to be attended to. Materials drawn from *comparative observation* should be collected, and every effort made by drawing together *comparative experimental results*, to prepare the way for some "master spirit," who, without doubt, will at some future time appear, to do that for naval architecture, which has been done for so many other branches of physical science.

Elements of different Ships.

Species of ship.	Burthen in lasts reduced into cubic feet, reckoning 91 cubic feet for each last.	Displacement in cubic feet to the outside of the timbers.	Length from the perpendicular at the stem to that at the stern post.	Greatest breadth to the outside of the timbers.	Distances of the load water line from the upper edge of the rabbet of the keel, at the frame ϕ.	Area of the midship section.	Depth of the keel measured from the upper edge of the rabbet.	Difference or draught of water.	Area of the load water line.	Quantity by which the centre of gravity of displacement is below the load water line.	$\frac{2}{3}\int\frac{y^3dx}{D}$.	Fraction of the distance between the centre of gravity of displacement and the load water line, when the centre of gravity of the ship and lading is below the water.	Distance of the metacentre from the centre of gravity of the ship and lading.	Moment of stability.

It is worthy of observation in reference to this table, how particularly the element x which represents the length from the perpendicular at the stem to that at the stern post, is connected with most of the other elements, and how readily the whole may be derived, by a logarithmic process, from the element P representing the burthen. For the purpose of assisting the young naval engineer in computing the various elements, we shall take the case of a frigate in which the value of P is equivalent to 45,500 cubic feet. From this, or any other assumed value, we may deduce step by step, by a very easy logarithmic operation, all the other elements of the table.

Value of the burthen P assumed $=$ 45,500 cubic feet.

Hence, to obtain the displacement D, we have, by applying logarithms to the function $P^{\frac{18}{17}}$ which represents it, $l\,P^{\frac{18}{17}}=\frac{18}{17}\,l\,4.6580114=l\,4.9320121$. Therefore, by passing from logarithms to numbers, we obtain the displacement $D=P^{\frac{18}{17}}=85509$.

To obtain the value of x, we have the expression $(56\,D)^{\frac{1}{3}}$, which, by logarithms, presents

$$l\,(56\,D)^{\frac{1}{3}}=\tfrac{1}{3}\,l\,(56\,D)=\tfrac{1}{3}\,(l\,56+l\,D)$$

$=l\,2.2267334$; and by passing from logarithms to numbers, we have $x=(56\,D)^{\frac{1}{3}}=168.55$.

To find the value of z, we have the function $\frac{x^{\frac{4}{5}}}{1.383}$, which, by logarithms, gives

$$l\frac{x^{\frac{4}{5}}}{1.383}=l\,x^{\frac{4}{5}}-l\,1.383=\tfrac{4}{5}\,l\,x-l\,1.383$$

$=l\,1.6405645$; and by passing from logarithms to numbers, we have $z=\frac{x^{\frac{4}{5}}}{1.383}=43.708$.

To obtain the value of h, we have the function $\frac{x}{8.1}$, which gives, by the application of logarithms,

$$l\,x-l\,8.1=l\,1.3182484;\text{ and hence}$$

$$h=\frac{x}{8.1}=20.809.$$

For the value of ϕ, we have the expression $\frac{1.705\,D}{x^{\frac{41}{40}}}$, and which presents the logarithmic form

$$l\frac{1.705\,D}{x^{\frac{41}{40}}}=l\,1.705\,D-l\,x^{\frac{41}{40}}$$

$$=l\,1.705+l\,D-\tfrac{41}{40}\,l\,x=l\,2.8813348.$$

Hence we have $\phi=\frac{1.705\,D}{x^{\frac{41}{40}}}=7.6091$.

For the value of k, we have the expression $\frac{x^{\frac{2}{5}}}{4.64}$.

Hence, by logarithms, we have $l\frac{x^{\frac{2}{5}}}{4.64}$

$$=l\,x^{\frac{2}{5}}-l\,4.64=\tfrac{2}{5}\,l\,x-l\,4.64=l\,0.2241754.$$

$$\text{Hence } k=\frac{x^{\frac{2}{5}}}{4.64}=1.6756.$$

To find d, the table furnishes the function $\frac{x^{\frac{3}{4}}}{23.3}$ which, by logarithms, gives

$$l\frac{x^{\frac{3}{4}}}{23.3}=l\,x^{\frac{3}{4}}-l\,23.3=\tfrac{3}{4}\,l\,x-l\,23.3=l\,0.3026943.$$

$$\text{Hence } d=\frac{x^{\frac{3}{4}}}{23.3}=2.0077.$$

To obtain W, we have the logarithmic expression

$$l\frac{z\,x^{\frac{31}{30}}}{1.49}=l\,z\,x^{\frac{31}{30}}-l\,1.49=$$
$$l\,z+l\,x^{\frac{31}{30}}-l\,1.49=l\,z+\tfrac{31}{30}\,l\,x-l\,1.49$$
$$=l\,3.7683360.$$

$$\text{Hence W}=\frac{z\,x^{\frac{31}{30}}}{1.49}=5865.9$$

For the value of V, we take the function $\frac{x^{\frac{7}{6}}}{48}$, and which, by logarithms, becomes

$$l\frac{x^{\frac{7}{6}}}{48}=l\,x^{\frac{7}{6}}-l\,48=\tfrac{7}{6}\,l\,x-l\,48=l\,0.9166144.$$

$$\text{Hence V}=\frac{x^{\frac{7}{6}}}{48}=8.253.$$

For S, we have the expression $\frac{x^{\frac{1}{2}}}{1.289}$. Hence $l\frac{x^{\frac{1}{2}}}{1.289}$

$$=l\,x^{\frac{1}{2}}-l\,1.289=\tfrac{1}{2}\,l\,x-l\,1.289=l\,1.0031138.$$

$$\text{Consequently S}=\frac{x^{\frac{1}{2}}}{1.289}=10.072.$$

We have now to find the value of L by means of the formula $\frac{49.65\,x^{\frac{1}{2}}-x^{\frac{7}{6}}}{64}$, which may be changed into $\frac{49.65\,x^{\frac{1}{2}}}{64}-\frac{x^{\frac{7}{6}}}{64}$.

Applying logarithms to the first of these quantities, we have

$$l\frac{49.65\,x^{\frac{1}{2}}}{64}=l\,49.65+l\,x^{\frac{1}{2}}-l\,64=l\,49.65+\tfrac{1}{2}\,l\,x-$$
$$l\,64=l\,1.0031060.$$

$$\text{Hence }\frac{49.65\,x^{\frac{1}{2}}}{64}=10.072.$$

Applying logarithms to the second quantity, we have

$$l\frac{x^{\frac{7}{6}}}{64}=l\,x^{\frac{7}{6}}-l\,64=\tfrac{7}{6}\,l\,x-l\,64=l\,0.7916756.$$

$$\text{Hence }\frac{x^{\frac{7}{6}}}{64}=6.1898.\quad\text{Consequently}$$

$$\text{L}=\frac{49.65\,x^{\frac{1}{2}}-x^{\frac{7}{6}}}{64}=10.072-6.1898=3.8822.$$

Finally, for the value of M we have the function

$$\frac{x^3}{56}\left(\frac{49.65\,x^{\frac{1}{2}}-x^{\frac{7}{6}}}{64}\right)=\frac{49.65\,x^{\frac{7}{2}}-x^{\frac{25}{6}}}{3584}$$
$$=\frac{49.65\,x^{\frac{7}{2}}}{3584}-\frac{x^{\frac{25}{6}}}{3584}.$$

Applying logarithms to the former of these quantities, we have

$$l\frac{4965\,x^{\frac{7}{2}}}{3584}=l\,49.65\,x^{\frac{7}{2}}-l\,3584=l\,49.65+l\,x^{\frac{7}{2}}-$$
$$l\,3584=l\,49.65+\tfrac{7}{2}\,l\,x-l\,3584=l\,5.9351182.$$

$$\text{Hence }\frac{49.65\,x^{\frac{7}{2}}}{3584}=861230$$

By a similar application to the latter quantity, we have

$$l\frac{x^{\frac{25}{6}}}{3584}=l\,x^{\frac{25}{6}}-l\,3584=\tfrac{25}{6}\,l\,x-l\,3584=$$
$$l\,5.7236878.$$

$$\text{Hence }\frac{x^{\frac{25}{6}}}{3584}=529280.\quad\text{Consequently}$$

$$\text{M}=\frac{x^3}{56}\left(\frac{49.65\,x^{\frac{1}{2}}-x^{\frac{7}{6}}}{64}\right)=861230-529280=331950.$$

Thus it appears that the vessel presented for examination, ought to have a displacement of 85509 cubic feet to the outside of the timbers; a length of 168.55 feet from the stem to the sternpost; a breadth of 43.708 feet to the outside of the timbers; a distance of 20.809 feet from the load water line to the upper edge of the rabbet of the keel; a superficial area of 760.91 feet for the midship section; a depth of keel from the upper edge of the rabbet 1.6756 feet; a difference of draught of water forward and aft of 2.0077 feet; a superficial area of 5865.9 feet for the load water section; a distance of 8.253 feet for the interval of the centre of gravity below the load water line; a distance of 10.072 feet for the interval between the centre of gravity and the metacentre; a distance also of 3.8822 feet between the metacentre and the common centre of gravity of the ship and lading; and finally, a moment of stability represented by 331950 feet.

In the first and second of the following tables, similar results of many ships of the same class, together with many others, are recorded.

Chapman has furnished us also with some valuable formulæ relating to the construction of privateers, and in which he has deduced all their necessary elements, from the weight of the guns, and the distance of the centre of gravity of the guns from the load water line.

In these formulæ he assumes A, C, and *c* as the elements alluded to; B the weight of the part above the water, comprising the masts, yards, sails, rigging, &c.; *a* the distance of the common centre of gravity of these weights from the load water line; D the displacement of the vessel to the outside of the timbers; *z* the breadth of the ship measured from the same parts; *y* the half breadth; *x* the length from the fore part of the stem to the after part of the stern post; *d* the depth of the ship, taken at the main section ϕ, from the load water line to the rabbet of the keel; and *k* the number of months for provisions.

Then Chapman asserts that the number of the crew may be represented by . . . . $3.763\,\text{A}^{\frac{5}{9}}$;

The weight of the crew by . . . . $10.16\,\text{A}^{\frac{5}{9}}$;

And their mechanical effect by . . . . $15\,\text{A}^{\frac{5}{9}}$;

The provisions also for *k* months, and water for half the time, wood, &c. by . . . $18\,k\,\text{A}^{\frac{5}{9}}$.

The formula for the time he finds to be $k = \frac{A^{\frac{2}{7}}}{2.756}$ and from which he derives the equation . . . $18\,k\,A^{\frac{5}{9}} = 6.534\,A^{\frac{53}{63}}$.
He has also found that the displacement is well proportioned, when $15\,A^{\frac{5}{9}} + 6.534\,A^{\frac{53}{63}} + A = K$, the displacement D being equivalent to $6.14\,c^{\frac{1}{4}}\,K^{\frac{13}{15}}$.
$B = \frac{D^{\frac{21}{20}}}{6.281}$ and the distance $a = \frac{D^{\frac{1}{3}}}{3.48}$.

In the next place, he assumes $C + 10.16\,A^{\frac{5}{9}} = Q$, and supposes the centre of gravity of displacement to be below the load water line by the quantity m, whose value he afterwards determines. Then the moment of stability, supposing the inclination very small, will be $\frac{2}{3}\int y^3\,d\,x - (m + a)\,B - (m + c)\,Q$.* But since $\frac{2}{3}\int y^3\,d\,x = (m + 6)\,D$, he finds that $(m + 6)\,D - (m + a)\,B - (m + c)\,Q = 6\,D$; and from which he derives $m = \frac{a\,B + c\,Q}{D - (B + Q)}$.

The same distinguished engineer also found the value of the stability to be $(m + 6)\,D$ or $\frac{2}{3}\int y^3 d\,x = \frac{z^3\,x^{\frac{21}{20}}}{26}$ and $z = \frac{x^{\frac{9}{10}}}{2.36}$. Hence also he derives $(m + 6)\,D = \frac{x^{\frac{15}{4}}}{341.8}$; and thence $x = \left(341.8\ (m + 6)\,D\right)^{\frac{4}{15}}$.

The area of the load water section he also finds should be $\frac{z\,x^{\frac{24}{23}}}{1.621}$; and the area of the main section $\phi = \frac{2.366\,D}{x^{\frac{13}{12}}}$. The value of d, moreover, he finds to be $\frac{x}{10.5}$. The centre of gravity of the ballast he supposes to be below the plane of the load water section, by a quantity equivalent to $\frac{x^{\frac{7}{5}}}{95}$; and the weight of the ballast he represents by

$$95\left(\frac{1.11 \times \left((m + a)\,B + (m + c)\,Q\right) - m\,D}{x^{\frac{7}{5}} - 95\,m}\right).$$

The moment of the sails with relation to the centre of gravity of the ship, or the plane of the load water line, he designates by the function $\frac{35.56 \times 6\,D}{x^{\frac{1}{3}}}$.

Such are the formulæ which this very celebrated man has, with infinite labour and research, deduced for the class of ships in question; but as a numerical example, at all times throws light on a subject presented in an algebraical dress, we shall select the instance he has given to illustrate their application.

For this purpose he assumes the following values, viz.

$$A = 2588,\quad C = 1815,\quad \text{and } c = 7.47;$$

which are adapted to a privateer of twenty-four twelve pounders on the main deck, eight four-pounders on the quarter deck and forecastle, with the lowest sill of the middle gun port, six feet above the water.

The logarithmic computations necessary for the application of the different formulæ, are exhibited in the following process.

To find the value of K, or that of $15\,A^{\frac{5}{9}} + 6.534\,A^{\frac{53}{63}} + A$, we have the separate expressions $l\,15 + \frac{5}{9}\,l\,A$, $l\,6.534 + \frac{53}{63}\,l\,A$, and A.

Hence l 15	=		1.1760913
$\frac{5}{9}\,l\,A$	=		1.8960913
and $15\,A^{\frac{5}{9}}$	=	1180.8	3.0721826
Also l 6.534	=		0.8151791
$\frac{53}{63}\,l\,A$	=		2.8712239
and $6.534\,A^{\frac{53}{63}}$	=	4857.4	3.6864030

Consequently $15\,A^{\frac{5}{9}} + 6.534\,A^{\frac{53}{63}} + A = 1180.8 + 4857.4 + 2588 = 8626.2$.

To find the value of D, we obtain by the application of logarithms to the proper expression $l\,6.84 + l\,c^{\frac{1}{4}} + l\,K^{\frac{13}{15}} = l\,6.84 + \frac{1}{4}\,l\,c + \frac{13}{15}\,l\,K$.

Or l 6.84	=		0.8350561
$\frac{1}{4}\,l\,c$	=		0.2183301
$\frac{13}{15}\,l\,K$	=		3.4110436
Hence D	=	29136	4.4644298

To find B, we have the expression $\frac{D^{\frac{21}{20}}}{6.281}$, which by logarithms presents the form of

$$l\,\frac{D^{\frac{21}{20}}}{6.281} = l\,D^{\frac{21}{20}} - l\,6.281 = \tfrac{21}{20}\,l\,D - l\,6.281.$$

Hence we have

$\frac{21}{20}\,l\,D$	=		4.6876512
l 6.281	=		0.7980288
and B	=	7755.7	3.8896224

To discover a, we have the expression $\frac{D^{\frac{1}{3}}}{3.48}$ and which by logarithms presents the form of

$$l\,\frac{D^{\frac{1}{3}}}{3.48} = l\,D^{\frac{1}{3}} - l\,3.48 = \tfrac{1}{3}\,l\,D - l\,3.48.$$

Hence $\frac{1}{3}\,l\,D$	=		1.4881433
l 3.48	=		0.5415792
and a	=	8.8423	0.9465641

* This expression is in some degree open to objection when the inclination becomes finite, it being then necessary to take into account the alteration made in the sides of the ship between wind and water.

To find Q, we have the expression $10.16\,A^{\frac{5}{9}} + C$, the application of logarithms to the first part of which presents,

$l\ 10.16$	$=$	1.0068937
$\frac{5}{9}\ l\ A$	$=$	1.8960913
Hence $10.16\,A^{\frac{5}{9}} = 799.81$		2.9029850

Consequently $Q = 10.16\,A^{\frac{5}{9}} + C = 799.81 + 1815 = 2614.81$.

To develope the value of m, the function $\dfrac{a\,B + c\,Q}{D - (B + Q)}$ presents for the application of logarithms the following:

$l\ a$	$=$	0.9465641
$l\ B$	$=$	3.8896224
Hence $a\,B = 68578$		4.8361865
And $l\ c$	$=$	0.8733206
$l\ Q$	$=$	3.4174385
whence $c\,Q = 19533$		4.2907591

And therefore $a\,B + c\,Q = 68578 + 19533 = 88111$.

$$\text{Hence } m = \frac{a\,B + c\,Q}{D - (B + Q)} = \frac{88111}{18765.49} = 4.695.$$

To obtain the value of x, we have the function $(341.8\,(m + 6)\,D)^{\frac{4}{15}}$, which adapted to logarithms, becomes $\frac{4}{15}\,(l\ 341.8 + l\,(m + 6) + l\ D)$.

Hence we have

$l\ 341.8$	$=$	2.5337721
$l\,(m + 6)$	$=$	1.0291808
$l\ D$	$=$	4.4644298
		8.0273827
		4
		15)32.1095308
		$2.1406354 = 138.24 = x$.

The expression for the ballast may be computed as follows:

$l\,(m + a)$	$=$	1.1315224
$l\ B$	$=$	3.8896224
Hence we have $(m + a)\,B = 104989$		5.0211448
$l\,(m + c)$	$=$	1.0141121
$l\ Q$	$=$	3.4174385
And also $(m + c)\,Q = 31736$		4.5015506

Consequently $(m + a)\,B + (m + c)\,Q = 136725$

Moreover $l\ 1.11$	$=$	0.0453230
And $l\,\{(m + a)\,B + l\,(m + c)\,Q = \}$		5.1358479

Hence we have $1.11\,((m + a)\,B + (m + c)\,Q) = 151764$ . . 5.1811709

Again, $l\ m$	$=$	0.6716356
$l\ D$	$=$	4.4644298
Therefore $m\,D = 136793$		5.1360654

And $1.11\,((m + a)\,B + (m + c)\,Q) - m\,D = 14971$.

Also $l\ 95$	$=$	1.9777236
And $l\,\{1.11\,((m + a)\,B + (m + c)\,Q) - m\,D\} = 14971$	$=$	4.1752508
Whence $95\,\{1.11\,((m + a)\,B + (m + c)\,Q) - m\,D\} = 1422245$		6.1529744

Moreover, for the denominator, we have

$\frac{7}{5}\ l\ x$	$=$	2.9968896
Whence $x^{\frac{7}{5}} = 992.86$		
And $l\ 95$	$=$	1.9777236
$l\ m$	$=$	0.6716356
Which gives $95\,m = 446.02$		2.6493592

Therefore $x^{\frac{7}{5}} - 95\,m = 546.84$

$$\text{Consequently } 95\left\{\frac{1.11\,((m+a)\,B + (m+c)\,Q) - m\,D}{x^{\frac{7}{5}} - 95\,m}\right\} = \frac{1422245}{546.84} = 2600.8 \text{ the ballast.}$$

To obtain the value of the stability, we have

$$\tfrac{2}{3}\int y^3\,dx = (m + 6)\,D.$$

Hence $l\,(m + 6)$	$=$	1.0291808
And $l\ D$	$=$	4.4644298
Wherefore $\frac{2}{3}\int y^3\,dx = (m + 6)\,D = 311611$		5.4936106

For the value of z, we have the function,

$$\frac{x^{\frac{9}{10}}}{2.36}, \text{ whence } l\,\frac{x^{\frac{9}{10}}}{2.36} = \tfrac{9}{10}\,l\,x - l\,2.36.$$

Wherefore $\frac{9}{10}\,l\,x$	$=$	1.9265719
$l\ 2.36$	$=$	0.3729120
Whence $z = 35.784$		1.5536599

To obtain the area of the load water-line, we have

$$l\,\frac{z\,x^{\frac{24}{23}}}{1.626} = l\,z + l\,x^{\frac{24}{23}} - l\,1.626$$
$$= l\,z + \tfrac{24}{23}\,l\,x - l\,1.626.$$

Wherefore $l\,z$	$=$	1.5536599
$\frac{24}{23}\,l\,x$	$=$	2.2337065
		3.7873664
$l\,1.626$	$=$	0.2111205
Whence $\dfrac{z\,x^{\frac{24}{23}}}{1.626} = 3769.2$		3.5762459

To find the area of the main section ϕ, we have the logarithmic expression $l\,2.366 + l\,D - \frac{13}{12} l x$.

Wherefore $l\,2.366$	=	0.3740147
$l\,D$	=	4.4644298
		4.8384445
$\frac{13}{12}\, l x$	=	2.3190217
Whence $\frac{2.366\,D}{x^{\frac{13}{12}}} = 330.69$		2.5194228

To determine d, we have $lx - l\,10.5$.

$l x$	=	2.1406354
$l\,10.5$	=	1.0211893
Whence $\frac{x}{10.5} = 13.166$		1.1194461

For the number of the crew, we have the expression $3.763\,A^{\frac{5}{9}}$, which, by logarithms, becomes

$$l\,3.763 + \tfrac{5}{9}\, l\,A;$$

Wherefore $l\,3.763$	=	0.5755342
$\frac{5}{9}\, l\,A$	=	1.8960913
Whence the number of the crew = 296		2.4716255

For the provisions we have $\frac{A^{\frac{2}{7}}}{2.756}$, whence, by logarithms we have $l\frac{A^{\frac{2}{7}}}{2.756} = \frac{2}{7}\, l\,A - l\,2.756$.

Wherefore $\frac{2}{7}\, l\,A$	=	0.9751327
$l\,2.756$	=	0.4402792
And the provisions	= 3.4265	0.5348535

The distance of the centre of gravity of the ballast below the load water line is represented by $\frac{x^{\frac{7}{5}}}{95}$, whence we have the logarithmic expression,

$$\tfrac{7}{5} l x - l\,95$$

$\frac{7}{5} l x$	=	2.9968896
$- l\,95$	=	1.9777236
Whence $\frac{x^{\frac{7}{5}}}{95} = 10.451$		1.0191660

The difference of the draught of water fore and aft $= \frac{x^{\frac{5}{8}}}{14.46}$, which, by logarithms, becomes

$$\tfrac{5}{8} l x - l\,14.46.$$

Wherefore $\frac{5}{8} l x$	=	1.3378971
$l\,14.46$	=	1.1601683
And $\frac{x^{\frac{5}{8}}}{14.46} = 1.5057$		0.1777288

Finally, for the moment of the sails, we have

$$l\,35.56 + l\,6 + l\,D - \tfrac{1}{3}\, l x.$$

$l\,35.56$	=	1.5509618
$l\,6$	=	0.7781513
$l\,D$	=	4.4644298
		6.7935429
$\frac{1}{3} l x$	=	0.7135451
Whence $\frac{35.56 \times 6\,D}{x^{\frac{1}{3}}} = 1202258$		6.0799978

Hence we have obtained the following elements for the vessel in question, rejecting the superfluous decimals:

The stability - - - - - - - -	311611
The length from the stern to the stern-post - - - - - - - - -	138.24
The breadth to the outside of the timbers - - - - . - - - - -	35.78
Ballast in cubic feet of sea water -	2600.8
Displacement - - - - - - - -	29136
Area of the loadwater line - - -	3769.2
Depth of the frame ϕ from loadwater line to rabbet of the keel - - -	13.17
Area of the frame ϕ - - - - - -	330.69
Number of crew - - - - - - -	296
Months for which provisioned - -	3.43
Quantity by which the centre of gravity of the ballast should be below the loadwater line - - - - - - -	10.45
Difference of draught of water - -	1.51
Moment of sails from the centre of gravity of the ship, or the loadwater line - - - - - - - - - -	1202258

And by the same methods are obtained the proportions of the sixteen ships recorded in the sixth of the following tables:

Proportions of Merchant Ships, calculated by the Rules in the preceding Table. No. 1. Frigates.

No.	Weight in lasts.	Displacement.	Length from stem to stern.	Breadth.	Area of midship section.	Draught of water at ⊕ on the keel.	Draught of water. Aft.	Draught of water. Forward.	Depth of keel.	Area of plane of load water line.	Quantity by which the centre of gravity is before the middle	Quantity by which ⊕ is before the middle of the length from stem to stern.
		cu. ft.	feet.	feet.	sq. ft.	feet.	feet.	feet.	feet.	sq ft	feet.	feet.

Proportions for Merchant Ships—Heckboats or Pinks. Sequel of the preceding Table. (No. 3.)

No.	Area of the plane of load-water line.	Quantity by which the centre of gravity is before the middle.	Quantity by which ⊕ is before the middle of the length from stem to stern.	Quantity by which the centre of gravity of displacement is below the water.	Distance of the metacentre from the centre of gravity of displacement.	Distance of the metacentre from the centre of gravity of the ship with lading.	Absolute moment of stability.	Number, which multiplied by the displacement, and divided by length from end to end equal the area of the frame ⊕.

Proportions for Privateers, &c. Sequel of the preceding Table, (No. 6.)

φ.	Quantity by which the centre of gravity of the displacement is below the water.	Height of the metacentre above the water.	Quantity by which the centre of gravity is before the middle.	Quantity by which φ is before the middle of the length from stem to stern.	Differences of the draught of water.	Quantity of ballast in cubic feet of sea water.	Centre of gravity of the ballast below the water.	Number of crew.	Months for which provisioned.	Moment of the sails with regard to the centre of gravity or to the water-line.	Height of the battery above the water.	No. which multiplied by the displacement, and divided by length from end to end, equal the area of frame φ.

The following Table contains the algebraical elements and numerical results of five classes of ships of the line. It is likewise derived from Chapman.

Elements for the Construction of Ships of the Line, by F. H. Chapman.

Nature of the Elements.		Algebraical Elements.	Ships of 110 Guns.	Ships of 94 Guns.	Ships of 80 Guns.	Ships of 74 Guns.	Ships of 66 Guns.
			Swedish feet.*				
isplacement to the outside of the timbers	=	D	152875	123257	107400	96422	88722
ength on the construction water line	=	$l = 5{\cdot}18454\ D^{0.3088}$	206.81	195.9	185.48	179.40	174.8
ddition on the ends	=	$\frac{l}{83} = f$	2.49	2.36	2.23	2.16	2.1
f this is added before	=	$\frac{7}{10} f$	1.74	1.65	1.56	1.15	1.47
nd abaft	=	$\frac{3}{10} f$	0.75	0.708	0.669	0.648	0.63
Vhole length of the water line between the rabbets	=	L	209.3	198.3	187.7	181.5	176.9
lain breadth on water line for three deckers	=	$\frac{l^{0.9947}}{3.5734}$ } $= B$	56.2	53.3	50.92	49.5	48.46
lain breadth on water line for two deckers	=	$\frac{l^{0.8392}}{1.5728}$ }					
First derived element	=	$\frac{D}{lB} = t$	13.13	12.28	11.37	10.85	10.47
Second derived element	=	$1.6303 t^{0.935} = t\,r$	18.11	17.90	15.82	15.15	14.65
xponent of the parabolic curve, expressing the areas of the transverse sections—(the less this exponent is, the sharper is the ship fore and aft)	=	$\frac{t}{tr - t} = n$	2.638	2.597	2.551	2.524	2.503
Main sectional area to the outside of the timbers	=	$B\,t\,r = \phi$	1019.2	906.9	806	750.4	719
Construction depth	=	$2.37402\ t\,r^{0.7047} = d$	21.75	20.72	19.26	18.94	18.49
Depth to the upper edge of rabbet of the keel	=	$1.503\ d^{0.87} = q$	21.9	20.98	20.02	19.46	19.03

* A Swedish lineal foot = .974 English lineal feet.
A Swedish square foot = .951 English square feet.
A Swedish cubic foot = .927 English cubic feet.

The foregoing tables suggest some important reflections. It is evident that Chapman entertained the idea of connecting together all the essential elements of naval architecture, by means of empirical formulæ, and of deriving all from some one primitive root or element. The bare conception of such an idea, marks the character of his mind in strong and original colours; and the steps he made towards its practical execution, stamp his name with double honour and renown.

The point to which naval architecture should continually approximate as a *limit*, ought to be the perfecting of the elements alluded to: obtaining for them more correct or appropriate co-efficients; establishing more completely their necessary relations, and throwing over the whole investigation a more accurate and philosophical character. No method of procedure, we would remark, can be more consistent with the legitimate and proper objects of philosophical inquiry. In the language of the modern analysis, it would be regarding every element of a ship, as a function of some one primitive element, and, by means of properly prepared co-efficients, deducing each one from it. There must, for example, be in every ship *some relation* between its length and displacement; so that by adopting one of them as its primitive term, the other by means of some multiplier or co-efficient, ought to be deduced from it. The breadth, too, must be a function of the length, and therefore some function of the displacement, if that element (and perhaps it is the best) be adopted as the primitive one. The area of the main section may also be so connected with the breadth, as to be resolvable at first into terms of the length, and ultimately into that of the displacement itself. In like manner, may the area of the plane of flotation, the moment of stability, the place of the metacentre, the position of the centre of gravity, and indeed the value of every other element of a ship, be ultimately traced to the displacement. If the whole length on the water line be denoted by l the entire length of the same line between the rabbets, must be some multiple of the same dimension; and as the former may be shown to be a function of the displacement, so may the latter. So that the displacement, or some other appropriate quantity, being assumed as a primitive element, every other element becomes connected with it; and no sooner is the *relation* of one part to another shown, than that relation becomes immediately connected with the element assumed. Hence adopting the language of functions we may say with Lagrange, that if the displacement be denoted by the primitive function $f\mathrm{D}$, in the series,

$$f\mathrm{D}, f'\mathrm{D}, f''\mathrm{D}. f'''\mathrm{D}, \text{ \&c.},$$

the derived functions of the same series,

$$f'\mathrm{D}, f''\mathrm{D}, f'''\mathrm{D}, \text{ \&c.},$$

may represent, successively, the other elements of a ship.

But it may be asked, in attempting to extend the investigation of these elements beyond the limits attained by Chapman, how are these *derived functions* to be obtained? We answer, by experiment and observation; by inquiring into the properties of the most approved models that have hitherto been produced; by *grouping* together facts, and drawing from their united testimony, legitimate results; pouring into the very heart of shipbuilding the genuine spirit of induction, and throwing over the whole of the inquiry the mantle of a pure philosophy; viewing facts, not as detached and insulated fragments, but as parts of a system which the progress of inquiry must eventually blend into one perfect and harmonious whole.

To those who may be disposed to deny the possibility of tracing, in the extended manner alluded to, the connexion of these different elements, we would observe, that some ships of war, and some vessels of our mercantile marine, possess confessedly better qualities than others. Some, indeed, possess a more than ordinary proportion of good qualities, and as such, become proper objects of *philosophical* examination. Suppose for example, that two or more ships of a particular class were selected, whose properties were generally recognised as good, might not many important conclusions be deduced from an analysis of their different elements? Each ship, for example, would have a given displacement, a length, a breadth a main sectional area, a certain stability, a particular position of the metacentre, a corresponding position of the centre of gravity, and indeed many other elements, each of which it would be highly proper to ascertain, and the relation of all of which to some primary element, it would be of the first importance to determine. These elements would, of course, at first possess a numerical character; but the generalizing eye of a philosopher would soon trace the existence of laws among the apparently unconnected arithmetical results; and order, and a system of definite relations, assume the place of irregularity, apparent accident, and chance.

To draw an example from the first of the tables before given, Chapman shows, in the case of a frigate, that the displacement is so related to the burthen estimated in cubic feet, as to present the conditional equation

$$\mathrm{D} = \mathrm{P}^{\frac{18}{17}};$$

or, in the second table, that the length is related to the displacement by an equation of the form

$$l = x\,\mathrm{D}^{y},$$

wherein l and D represent the elements referred to, and x, y, are unknown or indeterminate quantities, which it is the proper business of well-directed experiments to disclose.

In like manner we may draw from the investigations of the same able engineer, that the breadth is related to the length by the expression

$$\mathrm{B} = \frac{lx'}{y'}$$

where l the length may be obtained from the conditional equation before given, in terms of the displacement, and x', y' are empirical quantities, owing their origin entirely to experiment and observation.

Hence we may perceive how important it must be to the interests of naval architecture, to obtain from ships of approved character and value, every element that may be desired; not however by theoretical inquiry, but by well-digested courses of experiment, and long trains of observation; tabulating all the results that successful industry may obtain, in approved, and intelligible forms; entering every conclusion not as a detached and insulated quantity, but as an element which bears some relation to every other step of the inquiry.

Hitherto it has been the practice of those connected with naval inquiries, to view the various elements of shipbuilding, too much in the light of detached and insulated quantities, and not as parts of a system which possess the most perfect and intimate relations, and incapable of separation from each other. How often, from the imperfect condition of our knowledge, are we obliged to give to our most laborious disquisitions on stability, on displacement, on the metacentre, and indeed to most of the elements of naval architecture, a detached and insulated character; unable to trace the gradually inductive steps by which one branch of the inquiry is led on to another; how one individual element of a system is related to the elements that surround it, and how it stands connected with the great whole, of which it forms a part. And in no view of the subject before us, is this remarkable circumstance more apparent, than when we speak of the dimensions of ships, and endeavour to connect together the elements which compose them.

No one we will venture to say, who investigates the present condition of naval architecture, can for a moment allow, that it has been benefited in any material degree, by the example which the great reformer of philosophy exhibited to the experimental world. There has been little of what may be truly termed *inductive inquiry*, displayed in its history; and it stands now almost as a solitary monument of the folly which guided the predecessors of Bacon, in the paths of experimental investigation. Yet, in no subject is there greater room for the application of the most rigid principles of the inductive logic, than this. Millions of ships have been constructed, but only here and there a successful example has been offered for our contemplation, as if to mock the implicit obedience we pay in the practice of naval architecture, to uncertain and ill-defined rules.

There is one subject more, however, while referring to the tables of Chapman, to which we would briefly advert, and that is *notation*. A simple inspection of these tables will show, that that celebrated man did not avail himself of all the advantages that this powerful and important instrument is capable of affording. There is more in notation, to adopt a common phrase, than first meets the eye. Simplicity, uniformity, generality—a capability itself of suggesting new relations and inquiries—these, and many other particulars, are connected with the question of notation. And when we have seen the march of whole departments of science retarded for years, by the use of barbarous and improper symbols, it is not too much to insist, that in the formulæ and equations of condition that may hereafter be created for the use and extension of naval architecture, some little attention sould be paid to the lights that the modern analysis has thrown on the great question of notation. The remotest element of a ship must be connected with some primitive element, by a series of unquestionable laws,—laws dark and mysterious it is true at present, but which the spirit of a genuine and pure induction will eventually illuminate and make clear. This remote element may, however, be traced to its primitive element by a shorter route, by one process of ratiocination than another; but by no better method than by the pure light of a legitimate notation, can the "line of shortest descent" to this great point be obtained.

Shipbuilding began to be particularly attended to in England in the reign of Henry the Seventh, who commenced the Royal Navy of England by building the Great Harry, which is said to have been the first ship built with two decks in this country. In the succeeding reign the foundation was laid for an extensive royal navy; and the Admiralty and Navy boards were constituted for the direction of naval affairs. In the early part of this reign, the Regent, of 1000 tons burden, with the Mary Rose of 500 tons, and several other vessels, were constructed. The Regent being burnt in an engagement with the French fleet in 1512, Henry the Eighth ordered a ship to be built of equal tonnage, carrying 700 men, and named Henry grace de Dieu. The principal defect of ships at this period appears to have been too great height above the water in proportion to the extreme breadth, while at the same time the lower tier of guns, was much too near the water's surface. The loss of the Mary Rose is attributed to the defect of her ports being very near the water: Sir Walter Raleigh says they were within sixteen inches of the water. The loss of this vessel led to the raising the lower deck ports higher from the water.

At the end of the sixteenth and the beginning of the seventeenth centuries, ships of war were divided into seven classes, at the suggestion of Sir Robert Dudley. He gave the dimensions of the vessels according to the services for which they were intended, all of them being constructed to draw very little water. The length of the first class called the galleon, was four times the breadth; and the lengths of the other vessels gradually increased in proportion to their breadth. The seventh class, called the *passa-volante*, intended entirely for velocity, had its length in what has been truly characterised the extravagant proportion of ten times its breadth. At the period referred to, the ships of all nations displayed a remarkable similarity,—a circumstance arising from the Venetian vessels having been adopted by most of the constructers of that time, as models of imitation. In the reign of James the First, Mr. Phineas Pett built the Royal Prince, of the burden of 1400 tons, and 64 guns. The keel of this ship was 114 feet, and her cross beam 44 feet. In the reign of Charles the First, a much larger ship was constructed, called the Sovereign of the Seas. The length of her keel was 128 feet, and her main breadth 48 feet. Her length from the fore end of the beak head to the after end of the stern, *a prora ad puppim*, 232 feet; and in height, from the bottom of her keel to the top of the lanthorn, 76 feet. *She bore five lanthorns, the biggest of which would hold ten persons upright; had three flush decks, a forecastle, half deck, quarter deck, roundhouse, and also galleries*. A general increase of the ships of the Royal Navy took place in this reign; and in 1677 the dimensions of the different classes of ships were established by government. In the year 1684, Sir Richard Haddock, the comptroller of the navy, directed a scientific inquiry to be made into the solid content immersed in the water, of a ship of each class, when laden, from a fourth to a sixth rate, and by subtracting the weight of the ship's hull, when launched, from the total displacement, to determine the true burden in tons it will carry, and to compare this correct tonnage with the nominal tonnage calculated by the rules then in use This appears to have been the first attempt at the scientific investigation of the elements of ships in this country.

The following tables are taken from Derrick's *Memoirs of the Royal Navy*.

DIMENSIONS OF SHIPS.

Mr. Derrick informs us that the dimensions of the establishment of 1755, recorded in the above table, were determined from the proposals which the Lords Commissioners of the Admiralty directed the Flag Officers, the Surveyor of the Navy, and the Master Shipwrights of the dockyards, after consultation, to lay before them of a scheme of dimensions and scantlings, and a draught of a ship of each class, to remedy the defects which English ships were said to possess, of being weak from a deficiency in the scantlings, of not being able to carry so great a weight of metal as foreign ships, of their lower guns being too near the water, and of their being crank. The ships built according to these proposals, it is said, carried their guns well, and possessed sufficient stability, but were formed too full in their after bodies, a defect which was removed in the ships built at the commencement of the war in 1756, when a farther increase of dimensions was made. The improvement in the ships built according to the established dimensions of 1745, does not appear to have proceeded from any alteration in the *relative* proportion of the dimensions of the preceding establishments in 1719, 1733, and 1741. The length of the ships of the first class on the gun deck, in the order of these four dates, appears to have been 3.48, 3.48, 3.5, and 3.49 times the extreme breadth, where very little difference exists in the relative dimensions. The improvement in these ships arose from the general increase of the dimensions by which the guns were raised further above the water, (even supposing their height from the keel to remain the same,) in consequence of the load water line being lowered, the displacement being increased only by the additional weight of the hull, other weights remaining the same; the stability being also increased, the ships would incline less under the same press of canvass.

Spain was the first nation which increased the dimensions of the different classes of ships to considerable extent; and France followed her example with better success. The capture of the Princessa, soon after the commencement of hostilities with the former country in 1739, carrying 70 guns, and being upwards of 1700 tons burthen, pointed out the propriety of increasing the dimensions of our largest class of two decked ships, which may be seen by the following table to be so much inferior to her. The large two decked ships of the French were also proved to be very fine and powerful vessels, and in many points superior to the English eighty gun ships with three decks. In several instances, ships captured by the French were found, when retaken by the English, to have had their force reduced from what they carried in our service. The admiralty consequently directed the eighty gun ships then in use, with three decks, to be substituted by two decked ships of 74 guns, whose dimensions were particularly considered, and care taken that their lower tier of guns should be six feet above the water.

Comparative Dimensions of three ships of different nations about the middle of the eighteenth century.

	Length on the gun deck.	Extreme breadth.	Burden in tons.	Length in proportion to the breadth.
	ft. in.	ft. in.		
Shrewsbury, English ship of 74 guns, launched in 1750,	166 1	47 1	1594	3.52
Magnanime, of 84 guns, captured from the French in 1747,	173 7	49 7½	1832	3.49
Princessa, of 70 guns, captured from the Spaniards about 1740,	165 1	49 8	1709	3.32

The increase of dimensions in the English ships of 74 guns, proceeded very slowly. Their general dimensions appear to have been confined to 168 feet 3 inches in length, 47 feet 4 inches in breadth, and 1644 tons burden. England did not possess any two decked ships carrying 84 guns till after the middle of the eighteenth century. The French and Spanish navies were long inferior to the English in their want of three deckers, of which experience taught them the largest classes were much too powerful for their largest two deckers. It was not till after the peace of 1763 that either France or Spain possessed a single ship of three decks. The English three decker, the Royal George, carrying 100 guns, launched in 1756, of 2046 tons burden, was built of superior dimensions to our preceding first rates, and commenced that increase of size which has been so successfully carried forward in modern ships, and which has not yet attained by any means its limit.

The following table shows the magnitude and relative dimensions of the principal classes of modern ships of several European nations. The length and breadth would have been taken at the load water section, if they could have been obtained for all the ships. There will be, however, no considerable error in comparing them according to the dimensions given in the table.

Comparative dimensions of modern ships of different nations.

Names of ships.	Number of guns.	Length on the gun deck of the line of battle ships, and on the lower decks of the frigates.		Extreme breadth.		Burden in tons.	Proportion of the breadth to the length.

Freya, frigate,	42	148	7	39	4	1022	$\frac{100}{377}$

"The advantage of giving large dimensions to ships carrying a certain force, arises," says Mr. Morgan in an ingenious disquisition on this subject, contained in the third number of his 'Papers on Naval Architecture,' from several causes. It enables them to possess great stability, and thereby to carry a great press of sail, with a comparatively small body immersed in the water; thus giving them a great moving force in proportion to the resistance they experience in moving through the water, which must increase their rate of sailing. Large dimensions in proportion to the number of guns, gives fine quarters to the men in action. It also enables a finer form to be given to ships below the water, so that they may have a good entrance forward, and a clean run aft to the rudder: and to have the form best calculated to present great lateral resistance to the water, which prevents the ship from making much leeway. This form below the water, in connexion with great stability, is very beneficial in enabling the ship to beat off a lee shore.

The greater expense arising from the increase of dimensions is, however, a disadvantage which renders it desirable not to carry this principle far beyond necessary limits. The number and weight of guns a ship is intended to carry, must be the foundation of the design. The total weight of a ship being found, a corresponding displacement must be given, and the height of the lower tier of guns, when the ship is fully stored and provisioned, fixed at not much less than six feet from the water's surface. The number of guns to be placed on a deck being determined, with such a distance between them as naval officers have found to be sufficient to work the guns conveniently in action, and the necessary length given before the foremost and abaft the aftermost port, the least length which can be given to the ship is found. The breadth in proportion to the length must then be determined, so that the stability may be sufficient to work the leeward guns in a strong wind. The draught of water being then determined, such as experience has found to be necessary to keep a ship of such a class up to the wind, the form of the body may be given according to the judgment of the constructer, the best calculated for producing the necessary qualities of velocity, lateral resistance, answering the rudder readily, &c. Should the total displacement be then found equal to the weight of the ship, the dimensions are determined according to the necessary limits. Whatever increase of dimensions beyond these limits may be given, to alter any particular property, must be at the disadvantage of additional expense.

From these tables also may be seen, the relative proportion between the length and breadth of the ships of different nations. The determination of the breadth to be given to any ship of which the length is fixed, is one of the most important considerations in the design. It is this dimension which principally affects the stability of ships,—a quality on which the efficiency of a man-of-war, as well as its safety, depend. Although in order to determine the true value of the moment of stability, it is necessary to find the correct volumes of the parts immersed and emerged by the inclination, yet the breadth being the principal element in the determination of the value of this property, a tolerably correct judgment of the relative stability of ships, if not very dissimilar in form, may be generally obtained by comparing their relative breadths. This property, *ceteris paribus*, continues Mr. Morgan, is proportional to the length and third power of the breadth; so that a very small addition to the breadth increases the stability as much as a very considerable addition to the length. The advocates for great length in proportion to the breadth of ships, assert that long and narrow ships are the fastest sailers. With the same moving power, that is, with the same quantity of sail, the long and narrow ship, under some circumstances, particularly with the wind aft or but little on the quarter, in light breezes and a smooth sea, may sail faster than a broader and shorter ship. But when a ship sails with the wind at any point between the limits of being close-hauled and on the quarter, the ship is necessarily inclined by the power of the wind on the sails, and requires sufficient stability to prevent the inclination becoming too great. A deficiency in stability is frequently of the most serious consequence: it may cause the loss of a ship on a lee-shore: it may prevent a ship in a stiff breeze, when engaged with an enemy, from using the leeward guns: in a chase it may render a ship incapable of carrying the necessary press of sail to come up with the enemy: by a ship heeling much, it brings the round part of the body into the water, and the keel and lower parts of the body, which oppose the greatest lateral resistance to the water, become more oblique to its direction, and the ship is consequently allowed to fall to leeward more than it would if less inclined; the effect of the force of the wind on the sails is also diminished by its direction being more oblique when the ship is inclined. The importance of a ship possessing great breadth in proportion to the length, to ensure sufficient stability, appears under these circumstances much more than to counterbalance the advantage, which, by having greater length in proportion to the breadth, might be obtained in velocity in light winds and a smooth sea. It may be observed, that too great stability is, on the other hand, dangerous by the great strain it brings on the ship, and the liability it gives of carrying away the masts. But this is an excess which is very rarely complained of: the more frequent defect appears to be a deficiency in this quality.

In the last column of this table is shown the breadths of the different ships in proportion to their lengths. In the ships of three decks, the relative breadths of the ships of the different nations is in the following proportion and order: of the Spanish ship $\frac{100}{358}$, of the Swedish $\frac{100}{372}$, of the French $\frac{100}{360}$, and of the English $\frac{100}{363}$; where the relative breadth of the Spanish ship is seen to be the greatest, and of the English ship the least. In the large class of ships of two decks, of 80 guns and upwards, the relative breadth is in the following proportion and order: of the Spanish ship $\frac{100}{362}$, of the Danish $\frac{100}{367}$, of the Swedish $\frac{100}{369}$, of the French $\frac{100}{375}$, and of the English $\frac{100}{376}$; where the relative breadth of the Spanish ship is seen to be the greatest, and of the English ship the least. The difference, however, in the relative breadth of the last two, the French and English ships, is very little, and if some other French eighty-fours had been taken instead of the Tonnant, the relative breadth of the French and English ships of this class would have been the same, the Ganges having been built after a French ship, the Canopus. In the smaller ships of two decks, the relative breadth is in the following proportion and order: of the English $\frac{100}{361}$, of the Spanish, Swedish and French $\frac{100}{365}$, and of the Danish $\frac{100}{373}$; where the relative breadth of the English ships is the greatest, and of the Danish the least. In the frigates, the relative breadth is in the following proportion and order: of the Spanish ship $\frac{100}{367}$, of the French Unité (while in the French service, the Imperieuse) $\frac{100}{375}$, of the English Latona (one of a numerous class in our service, built after the old Leda) $\frac{100}{376}$, of the Danish $\frac{100}{377}$, of the Swedish $\frac{100}{379}$, of the French Niobe $\frac{100}{383}$, and of the English Portland $\frac{100}{393}$; where the relative breadth of the Spanish frigate, is seen to be the greatest, and of the English 60 gun frigates the least. The relative breadth of the French frigates taken during the last war, is generally nearer that of the Niobe than of the Unité.

From this comparison, continues Mr. Morgan, it appears that the relative breadth of our 120-gun ships is less than that of the three-decked ships of the other nations; that the relative breadth of our large class of two-decked ships agrees nearly with that of the French, and is less than that of the ships of the other nations; and that the relative breadth of the 60-gun frigates is considerably less than that of the frigates of other nations, and of most of our own frigates. The relative breadth of the Latona stands high in the order of the ships of their respective classes.

It does not appear, from this table, that any regularity exists in the proportion between the length and breadth of ships according to their magnitude. Whether ships, as they increase in magnitude, should have greater or less relative breadth in proportion to their length, does not appear to have been attended to as a general principle in the designs of the ships of different nations. In the Spanish ships, the relative breadth of those of three decks is greater than that of the ships of two decks, and the relative breadth of the larger Spanish and Danish ships of two decks is greater than that of the smaller ships of two decks, and the relative breadth of the two-deckers is greater than that of the frigates. In the ships of the other nations, the contrary is more frequently adopted, although very irregularly.

The first consideration respecting the relation between the length and breadth of ships of different magnitude, is, whether large or small ships require the greater relative stability. Now suppose a larger and smaller ship to have their moments of sails in proportion to their stability, and the height of their lower tier of guns to be the same from the water's surface, when they are upright; while these two ships would then be inclined, by the force of the wind on the sails, to the same angle, this inclination might be dangerous to the larger ship, but quite safe to the smaller ship, the sides of the two ships above the water being immersed nearly in proportion to their breadth. Supposing the breadth of the larger ship to be 50 feet, and of the smaller 40 feet, and the height of the lower ports in both ships to be six feet from the water's surface, when the lower ports of the smaller ship are, in consequence of the inclination, two feet from the water, the lower ports of the larger ship are only one foot from the water.

Supposing that the moment of sails is given in a proper proportion in the smaller ship, a smaller moment of sails in proportion to their relative stability must either be given to the larger ship, or a greater moment of stability, retaining the same moment of sails. For the sake of velocity, it is desirable that the stability of the larger ship should be increased.

Suppose the two ships to be similar, the one carrying two tiers of guns, the other three. The stability being in the proportion of the fourth power of the simple dimensions, if the centres of gravity of the two ships were raised above the centres of gravity of the displacements only in proportion to the dimensions of the ships, the stability of the larger ship would be increased in a much greater proportion than in the smaller ship; but as the centre of gravity in the large ship is raised by the additional deck and tier of guns higher than in the proportion of the dimensions, the stability is increased in one way and diminished in another. The effect of these elements of the stability on the value of its moment should be correctly ascertained. Probably, on the whole, the stability of the larger ship may generally be rather increased than diminished by the alterations, but not sufficiently without a little increase of relative breadth. This, however, could be obtained by calculation and experiments on other different classes of ships, and would be valuable information for the determination of the relative dimensions of ships of different sizes.

By comparing the dimensions in this table with those of the three ships given in a former table, it appears that the breadth of ships in proportion to their length is less in this table than in those which were built about the middle of the last century. The relative breadth of the Spanish ship appears to have been then, as well as at later periods, the greatest in proportion to the length; the relative breadth of the English ship in proportion to the length appears to have been considerably less than that of the Spanish, and a little greater than that of the French ship. By the table also, it appears that the relative breadth of English ships in proportion to their length was increased in the establishment of 1706 from the dimensions of preceding establishments, and that this relative increase continued with very little alteration till 1745. Towards the end of the last century a decrease of their relative breadth was introduced, which has influenced most of the subsequent designs. The breadth of the largest ships, by the establishment of 1745, varied from $\frac{100}{349}$ to $\frac{100}{355}$ the length; at the present time, the breadth of most of our line of battle ships is within the limits of $\frac{100}{361}$ and $\frac{100}{382}$; by which it appears that the relative breadth of our line of battle ships is considerably less at present than it was at that period.

The proportional breadth which should be given to ships is very materially affected by the consideration of the number and weight of the guns which they are intended to carry; as the greater the number of guns, and the greater their weight, the more is the stability diminished by the greater elevation of the centre of gravity of the ship, which must be counteracted by a corresponding increase of breadth. The best disposition of force as to the calibre of the guns to be used on board different ships, is a very difficult subject, and particularly requires, Mr. Morgan observes, the opinion of experienced and scientific naval officers for its determination. It appears to be generally admitted, that the effect of large shot is much more destructive than that of a greater number of smaller shot, making together the same weight. The limit to which the size of the guns on board ship may be carried with advantage, is bounded by the consideration of the number of hands required to work them, the convenience of handling the shot in action, the strain brought on the beams and ship's sides by their weight, and the effect they produce on the stability of a ship. The height of the guns above the water influences very materially the stability; and while particular attention should be paid, that the lower tier should be at a sufficient height to use the leeward guns under all circumstances in which they may be required, the upper tiers should be kept as low as possible.

The establishment of guns in 1757 and 1762, directed in the first rates, 42-pounders on the lower deck, 24-pounders on the middle deck, and 12-pounders on the upper deck. The establishment of 1792, directed 32-pounders on the lower deck, 24-pounders on the middle deck, and 18-pounders on the upper deck. It appears that 42-pounders have been considered too heavy for use on board ship. The large line of battle ships of the Americans* carry long 32-pounders on the lower deck, short 32-pounders on the upper deck, and 32-pounder carronades on the quarter deck, waist, and forecastle. The advantage proposed by this disposition of force, is the great weight of metal of a broadside, and the prevention of mistakes in the size of the shot in action. The principal force of large ships being chiefly required in general action, and at short distances, the short 32-pounders and the carronades are adopted as giving a very efficient force. The total weight of metal of a broadside of an English 120 gun ship is 1520 lb.; the weight of metal of one of these American two decked ships, carrying guns in the waist, is 1600 lb. The English first rate has thus the appearance of a greater force than it possesses, from the smallness of the weight of metal of many of the guns. To concentrate the weight of metal appears desirable, not only as preventing incorrect comparison, but as giving the most efficient force, and as affording the means of keeping the weight of the guns low.

The most important consideration respecting any proposed disposition of guns, is to place the lower tier at such a height as to be at a sufficient distance from the load-water-line, and to give the ship such breadth as to ensure a proper moment of stability.

The advantage of dividing the ships of the royal navy into as few classes as the different services would admit, has been frequently recommended as very desirable, particularly as relates to the appropriation of stores and gear. Experience may eventually determine the classes, into which the royal navy might be advantageously divided. Such a division must, however, always be subject to alteration from previously unforeseen circumstances; such, for instance, as the adaptation of steam vessels to the purposes of war, &c. Ships of three decks might probably be confined to one class, having a little greater breadth, and a little more height from the lower deck to the load-water-line than our present first rates. Ships of two decks may also probably be confined to one class, carrying 84 guns, as our present ships Ganges and Asia, with a little increase of breadth. Frigates might, perhaps, be confined to two classes, the larger carrying 60 guns,

* "Mr Morgan was on board one of these ships, the Washington, at New York, a few years ago, which carried 100 32 pounder guns and carronades: 32 long 32-pounders on the lower deck, 34 short 32 pounders on the upper deck, and 34 32-pounder carronades on the quarter-deck, waist, and forecastle."

of about the same length as our present frigates of this class, and of a greater breadth; and the smaller class of 46 guns, of nearly the same length and breadth as our present frigates of this force built after the Leda. The present 28 gun frigates are generally considered a bad class, having too great a height above the water in proportion to the part of the body below; the same defect which the old 80 gun ships with three decks, and the 64 gun ships with two decks possessed. This cannot be fully corrected without their dimensions being so considerably increased, as to render it questionable whether their expense might not be too great for their relative utility. A large class of corvettes, similar to some built in America, carrying 24 or 26 guns, might in many services substitute these small frigates, and be a powerful and useful ship in the service. Our corvettes of 18 guns fully substitute the 18 gun brigs, found too large for their rig, and are useful vessels for general service. The present 10 gun brigs, which are found good sea boats, might be the last class. These seven classes, with cutters and other small craft, might probably constitute advantageously the royal navy.

There appear to be limits, beyond which the magnitude of the three great divisions of the navy into ships having one, two, or three decks, cannot be carried, without injuring their properties, and increasing the expense of construction, equipment, and wear and tear, to an extent incompatible with their respective force and general service. If a nation does not possess ships of each of these three divisions, of the greatest magnitude of the respective limits, which although not yet correctly defined, experience has advanced far towards approximating to, it may be surprised in wars with other nations, by having to oppose, with great inconvenience and additional expense, and perhaps ineffectually, the smaller ships with two decks to the largest ships of one deck, and ships with three decks to the largest ships with two decks. The large ships with two decks, of 84 guns, and the large frigates of 60 guns, may probably have arrived near the greatest limits of magnitude of these divisions, and therefore would prevent surprise by new classes of ships of other nations.

To illustrate the loci of certain remarkable points connected with the formation of a vessel, Chapman constructed an ingenious figure, and which we have given in Fig. 1, Plate CCCCXCIV, for the information of our readers. Its description is as follows:—

On the load water line AB, a series of intervals 20, 40, 60, 80, 100, &c. are assumed as representatives of different lengths from the stem to the stern post of a vessel. Chapman then found, that in the case of a bark, the locus of the centre of gravity of displacement would be denoted by the line CGB, the locus of the metacentre by DDB, and that of the centre of gravity of the ship and lading by EEB. In the case of a frigate, he found FFB to be the locus of the centre of gravity of displacement, GGB that of the metacentre, and HHB that of the ship with its lading. So that for a vessel of the form of a bark 80 feet long, the distance from the load water line to the centre of gravity of displacement, would be denoted by LC; the height of the metacentre above the load water line by LD, and the depression of the centre of gravity of the vessel with its lading, below the load water line, by the quantity LE. But for a frigate, the distance of the centre of gravity of displacement below the load water line would be LF, the height of the metacentre above the same line LG, and the distance of the centre of gravity of the ship and lading below the water, LH. The length of the mainmast, moreover, is determined by the distance of the line HB from the same plane BA, so as to be of a magnitude corresponding to the stability.

If there be given to large and small ships, a form similar to that which is 110 feet in length, the straight line MB in the figure will represent the locus of the metacentre, and the line K K B the curve which will determine the length of the mainmast, so as to be in its proper relation to the stability.

In the formation of these curves, Chapman has introduced one supposition not strictly proper, and that is a uniformity in the density of the lading, a condition which, it is manifest, cannot in all cases be fulfilled. The graphic representations, however, he has given will be found of very essential service in the practice of shipbuilding. It would be possible to construct a series of curves for ships of the same class, which should embrace the important condition of a variable density in the lading.

Experience has taught us that the place of the midship bend exercises a very sensible influence on the properties of a ship; its situation depending more or less on the form of the extremities.

This will be apparent, if we compare a body composed of two wedges joined at their bases, and the place of whose centre of gravity is given, with another body of the same length, but composed of two hemispheroids; then it will be found, that the lengths of these spheroids will not bear the same proportion to the whole length as those of the wedges; or, in other words, the greatest breadths of the two bodies will be at different distances from their extremities.

To approximate in some degree to the situation of the midship bend, let ADBI, Fig. 2, Plate CCCCXCIV, represent the body of a ship, in which DI is supposed to denote the position of the section desired, and ADF, AIF similar parabolas, and BDF, BIF other like curves of that kind. Let C moreover be the middle point of the length from the stem to the stern post; E the centre of gravity of the entire vessel;* G the centre of gravity of DAI *before* the greatest section, and H the centre of gravity of the other portion of the vessel, abaft the same plane.

Assume AB, the entire length of the vessel $= a$, FA the distance of the midship section from the extremity $A = x$, and CE the interval between the middle point of the length, and the centre of gravity of the vessel $= m$. Now, by the property of the parabola, the distance of its centre of gravity G from the point $A = \frac{5}{8}$ AF, and FH $= \frac{3}{8}$ FB. Moreover, the areas of the parabolic spaces ADI, BDI vary as x and $a-x$; and referring every thing to the point A, we obtain the equation $\frac{5}{8}x^2 + (x + \frac{3}{8}(a-x))(a-x) = a(\frac{1}{2}a - m)$, which furnishes, by the ordinary processes

* Assuming the position E of the centre of gravity of the vessel is not rigidly correct; but the error is of no great moment, and it simplifies the investigation.

of algebraic reduction, the value of $x = \frac{1}{4}a - 4m$; and from which it follows, that the distance between the middle of the length of the ship, and its greatest section, ought to be four times the distance between this middle point and the centre of gravity of the ship. In a ship fuller at its extremities, so that $AG = \frac{7}{12}AF$, the distance of the greatest section from the middle $= 6m$. Should it be still fuller, so that $AG = \frac{9}{16}AF$, the distance of the greatest section before the middle point will be $8m$.

Hence it is seen, says Chapman, that the greatest section should be before the middle of the length for sharp ships, as frigates, four times the distance of the middle point of the length from the centre of gravity of the ship; and for merchant ships, which are very full, eight times the same distance.

This is the place of the midship bend, when the distances are estimated on the load water line; but if they are taken on the upper part of the keel, to which the frames are commonly placed perpendicular,† the midship bend ought to be a little before the greatest section, by a quantity depending on the difference of the draught of water forward and aft, and on the curvature of the ship at the middle.

This distance may be considered, in general, as equal to the difference of the draught of water.

OF THE SCALE OF SOLIDITY.

By a scale of solidity, we are to understand a method employed by naval architects, for ascertaining the displacement of a ship, at different depths below the load water line, by means of a curve, whose abscissæ correspond to the respective draughts of water, and ordinates to the displacements at the same points.

To construct a scale of solidity for the vessel whose entire displacement was before calculated, we must have recourse to the last column of the general table of results, named "Total Areas of Semi-Horizontal Sections."

If we refer to the table of results here quoted, and to the second figure of Plate CCCCLXXXVIII, we shall, in the first place, perceive that the *total* displacement of the vessel, or, in other words, the displacement *below* the load water line 1°, amounts to 100977.93 cubic feet, or 2885.08 tons; and that to ascertain the displacement *below* the horizontal section 2°, we must deduct from the total displacement, the solidity of the part comprised between the sections 1° and 2°. In performing the subsequent calculations, the areas of the semi-horizontal sections contained in the column above referred to, must be doubled to obtain the *total* areas of the horizontal sections, and also the total displacements.

To obtain the contents of the solid between the horizontal sections 1° and 2°, it is manifest, since the interval between the sections is one foot, that the mean of the two, or $\frac{7517.42 + 7438.64}{2} = 7478.03$ cubic feet is the quantity desired; and that by subtracting this result from the total displacement, and dividing the result by 35, there will remain 2671.43 tons for the displacement of the vessel *below* the horizontal section 2°. Hence it appears, that by decreasing the draught of water one foot, the displacement will be diminished 213.65 tons.

To determine, in the next place, the displacement below the horizontal section 3°, the solidity between the sections 1° and 3° must be determined, and the result subtracted from the total displacement. This must be accomplished by means of the formula $(\Sigma + 4\,S + 2\,s)\frac{i}{3}$, and for which in the present case, we have the following elements:

Extreme Areas.	Even Area.	Odd Area.
7517.42	7438.64	
7335.24	4	
14852.66 = Σ	29754.56 = 4 S	Zero.

And since $\frac{i}{3} = \frac{1}{3}$, we shall have $(\Sigma + 4\,S + 2\,s)\frac{i}{3}$

$= (14852.66 + 29754.56 + 0.0) \times \frac{1}{3} = 14869.07$,

for the solidity of the part required. Hence, by taking this from the total displacement, and reducing the result into tons, we shall have 2460.25 tons for the displacement of the vessel *below* the section 3°. So that by decreasing the draught of water 2 feet, the displacement is diminished 424.83 tons.

Again, to determine the displacement *below* the horizontal section 4°, the solidity of the part contained between the planes 3° and 4° must be first determined, and to it added the solidity of the part between the sections 1° and 3° before determined, and the sum taken from the total displacement.

The solidity between the sections 3° and 4° is evidently $\frac{7335.24 + 7204.54}{2} = 7269.89$

Solidity between the sections 1° and 3° before determined $= 14869.07$

Solidity between the sections 1° and 4° $= 22138.96$

Hence $\frac{109977.93 - 22138.96}{35} = 2252.54$ tons,

which is the displacement *below* the horizontal section 4°. Thus, by decreasing the draught of water 3 feet, the displacement is diminished 632.54 tons.

To determine, in the next place, the displacement *below* the section 5°, recourse must be again had to the formula for equidistant ordinates, by which means we have

Extreme Areas.	Even Areas.	Odd Area.
7517.42	7438.64	7335.24
7046.80	7204.54	2
14564.22 = Σ	14643.18	14670.48 = 2 s
	4	
	58572.72 = 4 S	

† It has been usual for constructers to place the different bends of timbers, at right angles to the line of the keel; a position, particularly in small ships, of the most objectionable kind, from the unnecessary strains to which the fastenings are exposed. Dr. Inman, the Professor of the College of Naval Architecture at Portsmouth, has with his usual judgment, placed the timbers of the Sapphire, one of the new experimental ships, *at right angles to the intended load water section*, a position sanctioned by the soundest principles of science.

and since $\frac{i}{3} = \frac{1}{3}$ we shall farther have

$(\Sigma + 4\ S + 2\ s)\frac{i}{3} = (14564.22 + 58572.72 + 14670.48) \times \frac{1}{3} = 29269.14$. Hence, by subtracting this from the total displacement, and reducing the result into tons, we have 2048.82 tons for the displacement *below* section 5°. Therefore, by decreasing the draught of water 4 feet, the displacement is diminished 836.26 tons.

Again, to obtain the displacement *below* the horizontal section 6°, we have

the solidity between the sections 5° and 6°

$= \frac{7046.80 + 6907.40}{2} = 6977.10$

Solidity between the sections 1° and 5° before determined $= 29269.14$

Solidity between the sections 1° and 6° $= 36246.24$

Hence $\frac{100977.93 - 36246.24}{35} = 1849.48$ tons must be the displacement below the horizontal section 6°. Therefore, by diminishing the draught of water 5 feet, the displacement is decreased 1035.6 tons.

To determine the displacement below the horizontal section 7°, we have

Extreme Areas.	Even Areas.	Odd Areas.
	7438.64	
7517.42	7201.54	7335.24
6617.16	6907.40	7046.80
14134.58=Σ	21550.58	14382.04
	4	2
	86202.32=4S	28764.08=2s

And since $\frac{i}{3} = \frac{1}{3}$, we shall farther have

$(\Sigma + 4\ S + 2\ s)\frac{i}{3} = (14134.58 + 86202.32 + 28764.08) \times \frac{1}{3} = 43033.66$. And by subtracting this result from the total displacement, and dividing the difference by 35, we shall have 1655.55 tons for the displacement below the horizontal section 7°. Thus, by decreasing the draught of water 6 feet, the displacement will be diminished 1229.53 tons.

By obtaining in this manner the displacements below the successive horizontal sections (applying the formula for equidistant ordinates, when the number of areas is *odd*, and when they are *even*, adopting the method above employed for ascertaining the displacements below the sections 4° and 6°) we shall obtain the numbers recorded in the first numerical column of the following table: and if we farther subtract each of these results from the total displacement, (2885.08 tons) we shall find the numbers entered in the second numerical column, and which denote respectively the successive alterations of displacement, produced by an uniform diminution of the draught of water.

Displacement of the Horizontal sections.		Decrease in the displacement produced by diminishing the draught of water.	
	Tons.		
Section 1°.	2885.08	Zero.	0. 0
Section 2.	2671 43	1 foot.	213 65
Section 3.	2460.25	2 feet.	424.83

To construct the desired scale of solidity, let the vertical line 1° B. Fig. 3, Plate CCCCXCIV. be drawn equal to 22.35 feet, the mean draught of water, measured from the under side of the false keel; and let this line be divided at equal intervals of a foot, at the points 2°, 3°, 4°, 5°, 6°, &c. corresponding to the intervals at which the foregoing displacements were computed. At the point 1°, erect the perpendicular line 1°A equal to 2885.08 tons, the displacement below the horizontal section 1°: and at the point 2°, the perpendicular 2°C equal to 2671.43 tons, the displacement below the horizontal section 2°; at the point 3°, the perpendicular 3°D equal to 2460.25 tons: at the point 4°, the perpendicular 4°E equal to 2252.54 tons; and through the remaining points 5°, 6°, 7°, 8°, 9°, &c. perpendiculars corresponding respectively to the displacements at those points. Then, if through the extremities A, C, D, E, &c. a fair and uniform curve be drawn, the scale of solidity will be completed, and the uses of which we shall now proceed to exemplify.

Suppose in the first place, the vessel were floating at her load water line 1°A, and that it were necessary for some purpose to diminish her draught of water four feet. Then since the line 1°A represents the displacement at the load water line, and 5°F the displacement corresponding to the point 5, or when the draught of water is diminished four feet; through F draw F*a* parallel to 1°B, and A*a* will represent on the scale of equal parts from which 1°A was laid off, the quantity of lading or stores to be removed, in order to reduce the draught of water to the desired quantity. The value of A*a* in the example selected will be 836.26 tons.

Suppose, in the next place the converse case were to occur, to ascertain what alteration would take place in the draught of water, by diminishing the lading by any given quantity, say 419 tons, when the load water line was denoted by 2°C. If on this water line, C*b* be laid off equivalent to the 419 tons, and through *b*, the line *b*E be drawn to intersect the curve of solidity in E, and E4° be drawn parallel to A1°, intersecting $1^\circ B$ in 4°, then will $2^\circ\ 4^\circ$, measured on the scale of equal parts, be the diminution of the draught of water desired, and which in the present instance is two feet.

Again, suppose a vessel had received some unknown portion of her lading, and it were required to ascertain by means of the scale of solidity, the exact quantity thereof. Let the mean draught of water be in the first place ascertained, and laid off from B to H; and through H let HI be drawn parallel to $1^\circ A$, meeting the curve of solidity in I. From I let IK be drawn perpendicular to $1^\circ A$. Then will HI, measured on the scale of $1^\circ A$, represent the actual displacement produced by the vessel and her present lading; and AK the quantity necessary to bring her down to the load water line $1^\circ A$. Also $1^\circ H$ will denote the depth to which the vessel will sink, in order to receive the portion of the cargo denoted by AK.

Suppose, lastly, that a vessel had received a known portion of her cargo, and it were required to ascertain the draught of water produced thereby. On the load water line $1^\circ A$, lay off $1^\circ L$ equal to the given displacement, and through L draw LM perpendicular to $1^\circ A$, intersecting the curve of solidity in M. Through M draw MN parallel to $1^\circ A$, intersecting $1^\circ B$ in N. Then will NB denote the mean draught of water required.

The uses therefore of scales of solidity are very great, and in the mercantile navy in particular, are of the highest importance. Every ship ought to have a scale of solidity constructed for it; and the more numerous the horizontal sections for which it is calculated, the better. It is probable, also, that if the properties of the curves of solidity of several vessels of each class of our men-of-war were investigated, some analytical relations might be discovered, of great importance to naval architecture.

It may be proper to remark, that in consequence of the great *numerical* disproportion between the *displacements* and their corresponding *draughts of water*, it is convenient in practice, to adopt different scales for those elements. For example, if $1^\circ A$, which in the present case is represented numerically by 2885, be measured by the same scale as that employed for the draught of water, the figure will be of an inconvenient size, unless the scale for the latter be assumed very minute, which will be attended also with disadvantage. The best way, therefore, is to adopt one convenient scale for the draught of water, and another for the displacement, but taking care in the application of the figure, to measure each by its own proper scale.

ON CALCULATING THE TONNAGE OF SHIPS.

The method of constructing a scale of solidity, naturally leads to the consideration of the mode by which the tonnage of a ship should be calculated; an interesting disquisition on which, we add from the pen of Mr. Morgan.

The propriety of having some scale by which the magnitude or capacity of ships may be compared with one another under one point of view, is universally acknowledged. Different causes, according to the services to which ships are applied, conduce to the propriety of a true method of comparison. If the number of guns a ship of war carries be correctly stated, and subject to no variation, and the number of guns should bear a constant relation to the magnitude of the body, the designation of a ship according to the number of guns might be sufficient for general purposes; as ships of war require chiefly to be compared with respect to their force.

The tonnage is generally used as a measure, by which ships built by contract are paid for. In order that this method of estimating the value of a ship may be correct, the relative alteration of any dimension should alter the tonnage in the same proportion, as it would effect the expense of building the ship. By the present method of measuring the tonnage, the increase of the breadth of a ship increases the tonnage in a much greater proportion than the expense of building. Though other rules may be given for calculating the tonnage of ships, which may be less incorrect as a scale of payment of building than the one at present in use, yet, as no correct analogy can be established between the tonnage and the expense of building, it appears desirable that some other scale of payment should be adopted, founded on more correct principles. If any part of the displacement of a ship be taken as a measure of the expense of building, it appears more reasonable that the weight of the hull, which is determined by the light displacement, should be taken, than the part of the displacement which is brought into the water by the lading. A better scale of the expense of building ships even than this may probably be determined by attention to this particular object, there being certainly no necessity that the same scale of measurement should be used for the lading and expense of building.

The disadvantage of paying for ships in proportion to their tonnage, is, however, no doubt, in a great degree corrected by a full examination of the design, previously to the settlement of the contract. In merchant ships, however this mode of payment is in numerous instances found to be injurious, by being the means of too little breadth being given to them in order to reduce the tonnage, and thereby lessen the expense of building.

A correct method of calculating the tonnage, although desirable for all ships for the sake of uniformity, is particularly necessary for merchant ships, which should always be compared by the true quantity of lading they can carry, in correct proportion to which their dues should be paid. The tonnage should be the correct measure of the number of tons of the lading of a ship. This is the weight that will bring a ship down in the water from the light water line, at which it swims when properly equipped with every thing on board, except the lading, to the load water line, at which it swims when laden.

This may be correctly found by determining the solid content of the body between the light and load water lines, the weight of which, considered as sea water, is the true lading; this solid divided by 35, the number of cubic feet of sea water in a ton, gives the true tonnage or weight of the lading.

The rule commonly used in England does not even approximate, on correct principles, to the true tonnage; the elements of the calculation being erroneously taken, the half breadth of the ship being substituted for the mean depth from the load to the light draught of water, and the divisor 94 substituted for 35, as a correction, though a very inadequate one, to this error.

Among the methods that have been proposed for the determination of the tonnage of ships, that of Chapman, in the eleventh chapter of his *Traite de la Construction des Vaisseaux*, is founded on the true elements of the calculation; it has, however, this serious disadvantage—that different divisors are taken at the will of the person who makes the calculation, according to his judgment of the relative fulness of the body between the load and light draughts of water.

That there would be considerable trouble in obtaining the correct tonnage of all the ships of the merchant navy, must be admitted: of the ships of the Royal Navy the trouble would be much less, as it could be calculated from the drawings by which they were built, which are always preserved in the Navy Office. But the correct tonnage, even of all merchant ships, might be obtained in a few years: and when the tonnage of the ships now afloat should be known, the great difficulty would have been surmounted, as the tonnage of every new ship could be calculated with comparatively little trouble. A scale of tonnage should be calculated for every ship, previously to its being launched, either from the drawing (if built from one), or from the ship itself. The light water line might be determined when the ship is fully equipped, with every thing on board except the lading, and transferred to the scale of tonnage previously made; the tonnage betwen this and the load water line would be the true tonnage, or weight of lading of the ship. The lading on board, when the ship swam at any intermediate line between the light and load water lines, would be immediately known by reference to the computed scale.

If it be objected, that many persons who are now capable of measuring the tonnage of ships would be unable to make these additional calculations, it may be answered, that as the number required to perform this service would be but small, sufficient persons might be found from those at present employed in this work, fully competent to undertake it: and indeed, that the calculations are so simple, that all might soon be perfectly acquainted with them.

Atwood gives in his paper on the stability of ships, in the *Philosophical Transactions of the Royal Society of London*, for 1798, p. 301, the tonnage of the *Cuffnells*, an East Indiaman, between the load water section and six successive horizontal sections below it, at two feet apart. The total displacement of this ship he determines to be 3410 tons.

The water-section, No. 12, is the load-water-section.

From the Water-Section.	Difference of Tonnage.	From the Water-Section.	Difference of Tonnage.
12 to 11	377 tons.	12 to 11	377 tons.
11 to 10	374	12 to 10	751
10 to 9	367	12 to 9	1118
9 to 8	357	12 to 8	1475
8 to 7	348	12 to 7	1823
7 to 6	333	12 to 6	2156

From these calculations a scale of tonnage may be formed, by which the weight of lading which would bring down this ship any distance between the load and light draughts of water may be immediately found.

The following method of calculating the tonnage of ships, although by no means superseding the propriety of scales of tonnage, may be considered superior to the rule at present in use, being founded on the true elements of the tonnage, the length and breadth of the ship, and the depth between the load and light draughts of water, and approximating very nearly to the true tonnage.

Let $a\,b$, Fig. 7, Plate CCCCXCII. represent the load-water-line, and $c\,d$ the light water-line; take the arithmetical mean of $a\,c$ and $b\,d$, which call e; let the length of the load water line, $a\,b$, be taken from the fore part of the rabbet of the stem to the after part of the rabbet of the stern-post, which call f; and let the greatest breadth at the load water line be represented by g. Multiply these three quantities together; then $\frac{x}{y} \cdot e\,f\,g$ will be the tonnage, in cubic feet, of sea-water, $\frac{x}{y}$ representing the fraction expressing the proportional part of the whole solid.

By obtaining the correct tonnage of different ships, by rules for calculating the contents of solids, it is found that $\frac{3}{4}$ may be substituted for $\frac{x}{y}$ subject to certain corrections, determined by reference to the ships whose tonnage is required. This correction may be most easily applied when reduced to a per centage, according to the different degrees of fulness of the part of the body contained between the load and light-water-lines, which may be determined by the following method:—

Draw $e\,f$ parallel to $a\,b$, and at a distance below it equal to half the mean of $a\,c$ and $b\,d$, and let $g\,t\,h$, Fig. 8, represent the horizontal view of this section; divide the whole length $g\,h$ into eight equal parts, and at the points of division draw $i\,q$, $k\,r$, $l\,s$, $m\,t$, $n\,u$, $o\,v$, and $p\,w$, perpendicular to the middle line $g\,h$. Take the sum of the lengths of these seven ordinates, and add to the part of the tonnage already found $1\frac{1}{2}$ per cent. for every one per cent. that this sum exceeds six times the length of the longest of these ordinates. This will give an approximate value of the tonnage to a great degree of accuracy.

Rule.

Take the length of the ship from the fore part of the rabbet of the stem to the after part of the rabbet of the stern-post at the height of the load water line, the greatest breadth of the ship at this height, and the mean depth between the light and load water lines; multiply these three dimensions together, and take $\frac{3}{4}$ the product, and divide by 35.

Then divide the length of the ship at half the mean depth between the light and load water-lines into eight equal parts, take the sum of the lengths of the seven half-breadths to the outside of the ship, and add to the above quantity $1\frac{1}{2}$ per cent. for every one per cent. this sum exceeds six times the length of the greatest of these half-breadths.

The result is the tonnage, or the weight in tons, that will be required to bring the ship down in the water from the light to the load-water line.

Example.

	Feet.
Length of a ship of 80 guns, from the fore part of the rabbet of the stem to the after part of the rabbet of the stern-post, at the height of the load-water-line . . .	181.75
Greatest breadth at this height to the outside of the plank of the bottom . .	50.25
Mean depth between the light and load-water-lines	7.83

Then $\frac{3}{4} \cdot \frac{181.75 \times 50.25 \times 7.83}{35} = 1532.4$ tons.

The sum of the seven half-breadths to the outside of the ship . .	161.5
The length of the greatest of these half-breadths	24.8

$24.8 \times 6 = 148.8$; then $161.5 - 148.8 = 12.7$.

12.7 is 8.5 per cent. of 148.8; and $1.5 \times 8.5 = 12.75$; then 12.75 per cent. of $1532.4 = 195.4$ tons.

Adding 195.4 tons to the first quantity, 1532.4 tons, the result, $1532.4 + 195.4 = 1727.8$, the required tonnage.

The light water line in His Majesty's ships can always be obtained by observation, and in merchant-ships it can be accurately taken when every necessary store is on board, including every thing but the lading, and entered on the register. There would be also frequent opportunities of proving the truth of it. Should this measurement be taken in any case when some of the stores (as anchors, cables, &c.) are not on board, proper deduction must be made for it in the calculation of the tonnage.

The principal trouble in this operation is the measurement of the half-breadths; but it requires only such a degree of attention as every one may be expected to pay who may be directed to perform the operation. The arithmetical operation is very simple, and may be as easily remembered as the present rule.

This rule admits of several modifications: a method less correct, but on the same principle, might be adopted by the measurement of the half-breadths on the lower deck, instead of the half-breadths at the horizontal section at the mean depth between the light and load water lines, or the measurement of fewer half-breadths might be taken; but the rule as above stated appears sufficiently easy for practice, particularly as greater correctness is always a sufficient reward for a little more trouble.

ON THE ARCHING OF SHIPS.

By the arching of a ship, we mean that alteration of form which every vessel undergoes from the moment it is launched. In every point of view in which the general problem of arching can be contemplated, it will be found to involve considerations of the highest importance to naval architecture. Owing its origin to those peculiarities of form, which the complicated conditions of stowage, stability, velocity, and general sailing qualities render necessary, it has been a great and principal object with the naval engineer, to preserve to the *floating* vessel unimpaired, those essential properties of form, which he endeavoured to impart to her in the process of *building*. Constructed, as ships in general are, of timbers of the most varied dimensions and forms,—disposed in directions of so many different kinds, and subjected to strains so changeable in direction and quantity, it may be fairly said, that next to the original determination of the best form, the skill and intelligence of the ship builder may be measured, by the degree in which the tendency to arching may be diminished. We shall hereafter have reason to admire the masterly combinations of Sir Robert Seppings, to prevent this derangement of the frames of our ships of war.*

We shall proceed to trace, by an inductive process, the operation of those forces that contribute to arching.

If, in the first place, an elastic body of any magnitude, specifically heavier than water, be wholly immersed in that fluid, no tendency to derange the figure or position of any of its axes will be produced, from the equal and uniform action of the water on its different surfaces. But if the solid be specifically lighter than water, and have consequently only a portion of its volume immersed, either of its axes,—whether it be longitudinal, lateral, or vertical, will be subjected to peculiar alterations of position and figure,—partly from the pressure of the fluid operating only on portions of its sides, and partly, if the form of the body be irregular, from the upward pressure of the water on its different vertical sections, not being equivalent to the weights of the sections themselves.

Let us, however, first take the case of a body, whose superior and inferior surfaces are equal, similar and parallel, and any vertical section of which is represented by ABCD, Fig. 1, Plate CCCCXCV. and let the line EF represent the surface of the water section, and therefore indicating the depth of the portion immersed.

Then since the upper and lower surfaces of the body are, by the hypothesis, equal, similar, and parallel, it follows that its sides are, in every part, perpendicular to the fluid surface. Suppose also the body to be composed of vertical laminæ of equal thickness, at right angles to the section ABCD, and let GH denote one of them. Then since the gravitating force of this lamina is exerted in the direction GH passing through its centre of gravity, and that this same line likewise passes through the centre of gravity of the column of fluid IH, displaced by the lamina: it follows from the laws of hydrostatics, that there will be an equlibrium between the gravitating force of the lamina, and the upward pressure of the fluid displaced by it: and that hence no derangement will take place in the particles constituting the lamina, from the influence of the pressure here alluded to. And since all the laminæ constituting the body are, by the hypothesis, similarly acted on by the fluid, it follows that no effort will be produced by the upward pressure of the fluid, to derange the form of the solid.

But suppose, in the next place, that some of the vertical laminæ, which make up the solid, should cease to preserve a perfect equality between the gravitating force and the upward pressure of the fluid; a case that would arise if a vertical section of the body were

* We cannot but regret that the important improvements connected with the trussed frame have not found their way more generally into our merchants' yards. It must be as beneficial to preserve a merchant ship from arching as a ship of war. We shall hereafter allude to some important considerations relating to the building of merchant ships.

of the form ABCD, Fig. 2, Plate CCCCXCV; some of the laminæ, as KL, receiving no upward support from the fluid, while their own gravitating powers remain undiminished: and others, as MN, deriving from the water only a partial support: it follows, that even if the sections between B and C could preserve their forms unchanged, those beyond the same points would by no means do so; and that, therefore, from the necessary adhesion existing among all the laminæ constituting the body, there would be a general tendency in the whole body to alter its form.

To investigate this new condition, let G denote the centre of gravity of the entire solid, and O that of its immersed volume; and let the line connecting those points be produced, so as to divide the entire solid into the two portions APQB, and DPQC. Now although, from the laws of hydrostatic equilibrium, the points G, O are situated in the same vertical plane, it by no means follows that the portion of the entire solid, APQB, and its immersed volume RSQB, in the present condition of the whole body, can have their centres of gravity in the same vertical plane. Hence we may imagine the centre of gravity of the former to be situated as at α, and of the latter as at β; the centre α, being, from the form of the body, necessarily farther from the vertical line PQ, than the centre β. In like manner, may we suppose the point γ to be more distant from the same vertical line PQ, than the point δ.

Now, the gravitating force of the solid APQB operating at α, and the upward pressure of the fluid at β, and that these forces act in opposite and not coincident directions; from those centres, let lines be drawn perpendicular to the fluid surface; and let W represent the gravitating effort of the body APQB, and w that of the fluid acting through β. Let also a similar construction be made with respect to the centres γ, δ, the weights W′, w' representing the mechanical efforts operating at those points.

If we now contemplate the effect of the forces acting at the points α, γ, it is apparent that their tendency is to *depress* the extremities of the body; whereas the action of the forces operating at the points β, δ, have a tendency to *elevate* its middle parts; and we know, from the theory of the neutral axis, that the ultimate effect of these forces must be, to make the entire body turn about a line of that nature, situated somewhere within the area of fracture, if the forces applied are capable of breaking the body; and which line, for the sake of illustration, we may suppose to be situated in the plane of the fluid surface at S; thereby causing all the fibres *above* that surface to be in a state of *extension*, and all *below* in a state of *compression;* while those fibres which pass through the neutral point S, undergo neither extension nor compression, but are in a state perfectly neutral with regard to both.

But if, in addition to the want of support afforded by the fluid to the inclined surfaces AB, CD, we imagine the vertical sections between B and C so constituted, as not in every case to be exactly in equilibrium with the columns of fluid displaced respectively by them; it is obvious that an additional tendency to arching will be created, and which we shall now more particularly investigate, by contemplating the actual conditions of a ship.

To discover the law which influences a ship, whether laden or unladen, when floating quiescently in water, we shall, in the first place, consider it with respect to its length, and afterwards in relation to its breadth.

To accomplish this, let us suppose a vessel to be divided into vertical sections of an indefinitely small constant thickness, perpendicular to the vertical longitudinal plane. If we commence our consideration at the stern, and advance gradually forward, it is evident that the sections comprising the counter and its connecting parts, being free from the water, will be subject to no reaction from it: and when at last any reaction of the fluid does take place, it must at first, from the peculiar form of the body, be infinitely less than the weight of the section whose displacement occasions it. As we approach, however, nearer the midship section of the vessel, the upward section of the fluid will approach more and more to an equality with the weight of its corresponding section, and ultimately become equal to it; and if we pass beyond this section, and which may be denominated the Section of Hydrostatic Equilibrium, we shall find the weight of the water displaced, become greater than the weight of the section above it. In like manner, if we commence at the bow of the vessel, we shall find a similar section of hydrostatic equilibrium, and afterwards a like increase of the weight of the water displaced above the weight of the section reposing on it.

Let us, therefore, in this very interesting inquiry adopt the investigation of Dupin, contained in his paper "*Sur la Structure des Vaisseaux Anglais,*" in the Philosophical Transactions for 1817.

For this purpose, let x represent the distance of any part of a vessel, from a vertical plane assumed as a standard of reference for the different moments, and let $d\,x$ be the thickness of the infinitely small sections parallel thereto. Let also $\varphi\,(x)\,d\,x$ denote the weights of those sections, and $\psi\,(x)\,d\,x$ that of the water which they displace. Then will the total moment of these forces be

$$x\,.\,\varphi\,(x)\,.\,d\,x - x\,.\,\psi\,(x)\,.\,d\,x,$$

and, consequently, the integral of the same system of moments

$$\int \Big\{ x\,.\,\varphi\,(x)\,.\,d\,x - x\,.\,\psi\,(x)\,.\,d\,x \Big\}.$$

Now, in order that this function may be either a maximum or a minimum, it is necessary that its variation should be zero, and which, therefore, produces the equation

$$\delta\int \Big\{ x\,.\,\varphi\,(x)\,.\,d\,x - x\,.\,\psi\,(x)\,.\,d\,x \Big\} = o.$$

But in this latter expression, neither of the original sections alters its weight; and the functions (x) and $\psi\,(x)$ remain constant, as well as the thickness $d\,x$ of the sections, only by removing the plane, with respect to which the moments are taken, to the distance $\delta\,x$ the section of which $\varphi\,(\delta\,x)$ represents the weight, and $\psi\,(\delta\,x)$ its displacement is added.

Hence we have

$$o = \delta\int \Big\{ \varphi\,(x) - \psi\,(x) \Big\}\, x\,d\,x = \int \Big\{ \tfrac{1}{2}\,\big[\varphi\,(\delta\,x) - \psi\,(d\,x)\big] + \big[\varphi(x) - \psi\,(x)\big] \Big\}\, d\,x\,.\,\delta\,x.$$

But since the functions $\varphi\,(x)$ and $\psi\,(x)$ become zero when we cause x to vanish,—these expressions represent the weight and displacement of a vanishing section; and hence we may perceive that $\phi(\delta x) - \psi(\delta x)$ becomes infinitely small when compared with $\phi(x) - \psi(x)$.

If, therefore, the expression $\phi(\delta x) - \psi(\delta x)$ may be neglected, much more may the function $\frac{1}{2}\left[\phi(\delta x) - \psi(\delta x)\right] d\,x \,.\, \delta x$; and hence the general expression representing the condition of either the maximum or minimum of the moments, which tend to produce arching, will be

$$o = \int \left\{\phi(x) - \psi(x)\right\} d\,x \,.\, \delta x,$$

or

$$o = \delta x \int \left\{\phi(x) - \psi(x)\right\} .\, d\,x,$$

in which $\int \phi(x)\, d\,x$ is the total weight of the sections under consideration, and $\int \psi(x)\, d\,x$ the total weight of the displacement of the same sections.

From this last equation of condition, we learn that the sum of the moments which tend to produce arching is either a maximum or a minimum, when the weight of the part of the vessel, either before or behind the plane of the moments, is equal to the weight of the water displaced by the same part of the ship.

It may be necessary, however, to distinguish the condition of the maximum from that of the minimum, and which may be discovered by the circumstance, that according as the term of the formula neglected has the *same* or a *contrary* sign from the expression for the total moment

$$\int \left\{\phi(x) - \psi(x)\right\} x \,.\, d\,x,$$

the sum of the moments, with relation to the plane determined, will be a *minimum* or a *maximum*.

But since $\phi(\delta x)\,\delta x$ is the weight of the section having δx for its thickness, and $\psi(\delta x)\,\delta x$ the weight of the water displaced by the same section, it follows that the quantity

$$\tfrac{1}{2}\left[\phi(\delta x) - \psi(\delta x)\right] .\, \delta x \,.\, d\,x$$

will be positive or negative, according as the weight of the infinitely small section, which commences at the plane of the moments, is greater or less than the weight of the water displaced by the section itself. From these principles we deduce the following theorems:

I. *That when a vertical plane divides a vessel into two parts, so that the weight of each part is equal to the weight of water displaced by it, the moments of those parts estimated in relation to the same plane, to produce what we have denominated arching, will be either a maximum or a minimum.*

II. *That this effect will be a maximum, when the infinitely small section contiguous to the plane of the moments, has its own moment in a contrary direction to that of the total moment.*

III. *That the effect will be a minimum when this section has its own moment acting in the same direction as the total moment.*

We shall proceed to the farther illustration of these theorems by their application to a seventy-four gun ship, the elements of which are derived from Dr. Young's paper on the employment of Oblique Riders, contained in the Philosophical Transactions for 1814.

Distribution of the forces operating on the hull of a seventy-four gun ship, when fitted for sea, its length being 176 feet, and breadth 47.5 feet.*

Length estimated on the plane of flotation, in feet.	Weights of the sections corresponding to those lengths in tons.	Displacements of the same sections in tons.	Differences between the weights of the sections and their displacements in tons.

* As many of our readers may be desirous of having the whole of the analytical investigation relating to this important subject, from the pen of Dr. Young, we add it in the following note.

The laws of equilibrium will not allow us to suppose the above forces concentrated in the middle of the respective portions, or equally distributed through them; and it becomes necessary, that one of the weights should be situated further forwards, which must be that of the foremost portion, containing the bowsprit and its rigging. It is also natural to suppose the excesses of weight and pressure distributed with as few abrupt changes as possible, so as to neutralise each other at the common termination of the adjoining portions, and to become more unequal in parts more remote from these neutral points. Thus the excess of weight in the first 49 feet being 72 tons, it may be supposed to begin at the rate of $\frac{144}{49}$ tons per foot, and to diminish gradually and equably, so that its centre of action will be at the distance $\frac{49}{3}$ from the end; the excess of pressure must increase in the next place, until, at the distance of 59 feet from the stern, it becomes $\frac{108}{10}$ per foot, and must then diminish until it vanishes at 69, where the excess of weight must begin to prevail, becoming at 94, $\frac{118}{25}$ per foot, and vanishing at 119. The excess of pressure might then be supposed to increase gradually through the next portion, in order to avoid an abrupt change at its extremity; but this supposition would still be insufficient, and it becomes necessary to imagine that for 6.6 feet the forces remain neutralised, and the pressure then prevails, so that its excess becomes at last $\frac{119}{6.7} = 17.7$ per foot; it must then decrease for 17.5 feet, and the excess of weight at the extremity must become 19.7 per foot, the neutral point being at 156.5. The equilibrium of the forces will then be expressed by the equation $72 \times 16.3 - 108 \times 59 + 118 \times 94 - 119 \times 134.5 - 155 \times 144.8 + 192 \times 169.5 = 0$

From this distribution of the forces, we obtain a determination of the strain from each point of the respective portions, which is in the joint ratio of the magnitudes and distances of all the forces concerned, on either side of the point, reduced into a com-

In order to distribute with some uniformity, the positive and negative differences recorded in the last column of the preceding table, M. Dupin has had recourse to a geometrical figure, and by an hypothesis, originally adopted by Dr. Young, in the paper before quoted, has assumed in the line AO, Fig. 3, Plate CCCCXCV. supposed coincident with the plane of the water's surface, certain segments AC, CE, EG, GH, HK, KM, and MO, having values equivalent to the quantities recorded in the first column of the succeeding table; and on those segments has supposed certain triangular areas to be formed, equivalent to the positive and negative quantities recorded in the last column of the former table. For example, on the segment AC is formed the right angled triangle ABC $=+72$; on CE, the isosceles triangle CDE $=-108$; on EG, the isosceles triangle EFG $=+118$; on HK the right angled HIK $=-119$; and on KM, MO the right angled triangles IKM, MON, the area of the former being -155, and of the latter $+192$; the difference of these areas being equivalent to $+37$, the last member of the column last refered to. The pomon result. For the first portion it is $\frac{144}{49}x \times \frac{1}{2}x - \frac{1}{2}\cdot\frac{144}{49}\cdot\frac{x}{49}x\,\frac{1}{3}x = \frac{72}{49}x^2 - \frac{1}{6}\cdot\frac{144}{49}\cdot\frac{x^3}{49}$, x being the distance from the stern; for the 2d, $72\,(x-16\tfrac{1}{3}) - \frac{1}{6}\cdot\frac{108}{10}\cdot\frac{(x-49)^3}{10}$; 3d, $72\,(x-16\tfrac{1}{3}) - 54\,(x-55\tfrac{2}{3}) - \frac{108}{20}\,(x-59)^2 + \frac{1}{6}\cdot\frac{108}{100}\cdot(x-59)^3$; 4th, $72\,(x-16\tfrac{1}{3}) - 108\,(x-59) + \frac{1}{6}\cdot\frac{118}{25}\cdot\frac{(x-69)^3}{25}$; 5th, $72\,(x-16\tfrac{1}{3}) - 108\,(x-59) + 59\,(x-94) + \frac{118}{50}\,(x-94)^2 - \frac{1}{6}\cdot\frac{118}{25}\,\frac{(x-94)^3}{25}$; 6th, from 119 to 125.6, $72\,(x-16\tfrac{1}{3}) - 108\,(x-59) + 118\,(x-94)$; for the 7th, we must add to this expression $-\frac{1}{6}\cdot\frac{119}{13.4}\cdot\frac{(x-125.6)^3}{13.4}$; and, in the last 37 feet, the strain will be expressed by $(176-x)\,19.7 \times \frac{1}{2}\,(176-x) - \frac{1}{6}\cdot 19.7\,\frac{(176-x)^3}{19.5}$. Hence we find the strain, at seven points, 22 feet distant from each other, and from the ends 605, 1993, 2815, 2244, 2655, 4610, and 1875; and by taking the fluxion of x in the seventh portion, we determine the maximum at $141\tfrac{1}{3}$ feet, amounting to 5261 tons, supposed to act at the distance of one foot. In order to form an idea of the curve which would be produced by such a strain acting on a uniformly flexible substance, we may consider the curvature as represented by the second fluxion of the ordinate y, and by finding and correcting the fluent separately for each portion, we may obtain the ordinate or fall at any given point corresponding to a given extent of arching of the whole fabric. It will, however, be sufficiently accurate for this purpose, to consider the forces as concentrated in a limited number of points, dividing those which act in the extreme portions into two parts, in order that the curvature may be continued to the ends; so that the whole of the forces may be thus distributed: at 0.36; at 32 2-3, 36; at 59, -108; at 94, 118; at 134·5, -119; at 144.8, -155; at 163, 96; and at 176, 96. The strain for each portion may then be represented by $a - b\,x$ whence $\ddot{y} = a\,\dot{x}\,\dot{x} - b\,x\,\dot{x}\,\dot{x}$, $\dot{y} = a\,x\,\dot{x} - \frac{1}{2}\,b\,x^2\,\dot{x} + c\,\dot{x}$, and $y = \frac{1}{2}\,a\,x^2 - \frac{1}{6}\,b\,x^3 + c\,x + d$. It will be most convenient, in calculation, to make x begin anew with each portion, setting out from the middle, and to divide the numbers by 100, in order to shorten the operations: thus, for the middle portion from 88 to 59, the strain will be $.2028 + .36\,x$, a being .2028, and $b = -.36$; and when x becomes .22, y is .00552, and when $x = .29$, $\frac{\dot{y}}{\dot{x}} = .0740$, and $y = .0011$; which values being substituted in the equations for the next portion, we have $c = .074$, and $d = .0011$; and by going through the whole length in this manner, we find the fall at the extremes and at seven equidistant intermediate points, .08697, .05325, .02514, .00552, 0, .00507, .02531, .06705, and .12325. If we wish to find the point at which the curve is parallel to the chord of the whole, we must enquire where $c = (.12325 - .08697) : 1.76$. which will be at 98 feet or 10 feet before the midships.

We must next determine the magnitude of the strain arising from the longitudinal pressure acting on the lower part of the ship only. The resistance being supposed to be proportional, in the first instance, to the degree of compression or extension, according to the common and almost necessary law of the constitution of elastic bodies, and varying also in the direct ratio of the strength of the fabric, which may be assumed to be either equable, or in the case of a ship, proportional to the distance from a point more or less remote, we must form an equation of equilibrium for the absolute equality of the forces in opposite directions, and another for their powers of acting with respect to any given point as the fulcrum of a lever. Thus the fluxion of the absolute resistance at the distance x from the upper surface, supposing the strength to be as $a + x$, and the neutral point, at which the compression and extension cease to be at the distance b, will be $(b - x)\,c\,(a + x)\,\dot{x} = c\,(a\,b - a\,x + b\,x - x\,x)\,\dot{x}$, which, when x is equal to the depth d, must become equal to the force f producing the strain, or $f = c\left(a\,b\,x - \frac{1}{2}\,a\,x^2 + \frac{1}{2}\,b\,x^2 - \frac{1}{3}\,x^3\right)$; and for the second equation, referring the forces to the upper surface as a fulcrum, the fluent of $c\,(b - x)\,(a + x)\,x\dot{x}$, must be equal to $e\,f$, e being the distance at which the force e is applied; whence $e\,f = c\left(\frac{1}{2}\,a\,b\,d2 - \frac{1}{3}\,a\,d^3 + \frac{1}{3}\,b\,d^3 - \frac{1}{4}\,d^4\right)$. Now if we make $a = d = x$, the equations become $c\left(\frac{3}{2}\,b\,d^2 - \frac{5}{6}\,d^3\right) = f$, and $c\left(\frac{5}{6}\,b\,d^3 - \frac{7}{12}\,a^4\right) = e\,f$, and from the former we have $c\left(\frac{5}{6}\,b\,d^3 - \frac{25}{54}\,d^4\right) = \frac{5}{9}\,d\,f$; and, by subtraction, $\frac{13}{108}\,c\,d^4 = \left(\frac{5}{9}\,d - e\right)f$; consequently the force f may be considered as acting on a lever of the length $e - \frac{5}{9}\,d$; and if we take any other value for a, the fractional multiplier of d, instead of $\frac{5}{9}$ will be $\frac{3\,a + 2\,d}{6\,a + 3\,d}$, thus if $a = \frac{1}{2}$, we have $e - \frac{7}{12}\,d$ for the length of the lever. In order to find the mean distance e at which the pressure of the water acts, we may suppose the form of the mean transverse section of the ship to be parabolic, and the area such as to correspond to the bulk of 3000 tons of water, each containing 35 cubic feet, the length being 176 feet, and the breadth $47\tfrac{1}{2}$, whence the depth must be 18.84 feet; then the centre of gravity of a parabola being at the sitive areas, it will be perceived, are formed below the plane of flotations, and the negative areas above it. These particulars are recorded in the next table.

Values of the segments making up the total length AO of the ship.	Areas equivalent to the differences between the weights of the sections and their displacements.
AC = 49	Surface ABC = + 72
CE = 20	Surface CDE = − 108
EG = 50	Surface EFG = + 118
GH = 6.6	Surface HHK = − 119
HK = 13.4	Surface IKM = − 155
KM = 17.5	Surface MNO = + 192
MO = 19.5	
Total AO = 176	Total = 000

In the next place, let the centres of gravity of the several triangular areas referred to, be determined, and from them let perpendiculars be demitted on the primitive line AO, meeting it in the points b, d, f, r, s, and n. The determination of these centres will furnish the elements of the following table; the comparison of the first and last columns of which, gives the respective distances of the common origin of the horizontal ordinates from the centres of gravity of the triangles.

$$\begin{aligned}
A\,b &= \tfrac{1}{3}\,AC &&= \tfrac{1}{3}\,49 &&= 16{\cdot}3\\
A\,d &= AC + \tfrac{1}{2}\,CE &&= 49 + 10 &&= 59\\
A\,f &= AE + \tfrac{1}{2}\,EG &&= 69 + 25 &&= 94\\
A\,r &= AH + \tfrac{2}{3}\,HK &&= 125{\cdot}6 + 8{\cdot}9 &&= 134{\cdot}5\\
A\,s &= AK + \tfrac{1}{3}\,KM &&= 139 + 5{\cdot}8 &&= 144{\cdot}8\\
A\,n &= AM + \tfrac{2}{3}\,MO &&= 156{\cdot}5 + 13 &&= 169{\cdot}5
\end{aligned}$$

This construction, therefore, furnishes for the equilibrium of the forces operating on the vessel, the equation

$$0 = 72 \times 16{\cdot}3 - 108 \times 59 + 118 \times 94 - 119 \times 134{\cdot}5 - 155 \times 144{\cdot}8 + 192 \times 169{\cdot}5,$$

being identical with that given by Dr. Young, at page 306 of the paper before referred to.

On this equation of equilibrium, M. Dupin makes many judicious observations. In the first place, he remarks, that the triangle EFG ought not to be regarded as isosceles, since its vertex is the point in which the difference between the weight of the section and its displacement is the greatest in this part of the vessel, and which point ought to correspond with the position of the main mast. But the main mast is situated abaft the middle point ϕ of the vessel, and is therefore nearer to the common point of origin, A by 19 feet $\left(=\frac{176}{2} - 69\right)$ than the central part of the ship. According to Dupin, the vertex of the triangle CDE is too far forward by at least 12 feet. In order also to make the sum of the moments vanish, Dr. Young was obliged to transfer a weight of 37 tons from the fore part of the ship to its displacement. These discrepancies arose from the imperfect nature of the data furnished to Dr. Young.

Let us, however, follow the steps of Dupin, and, retaining still the hypothesis of Dr. Young, apply the theorems before investigated, to the determination of the sections, which indicate either a maximum or a minimum. For this purpose, since the area of the triangle ABC was designated by + 72, and that of the triangle CDE by − 108, we must endeavour to draw within the latter triangle a line such as P p, which shall cut off from it the negative area CDP p, equal numerically to the area of the triangle ABC. Since, therefore, the area of the trapezium CDP p is, by this supposition, equal to −72, it follows that the area of P p E = −36; and since similar triangles are to each other in the duplicate ratio of their homologous sides, we have

$$\triangle\,D\,d\,E : \triangle\,P\,p\,E :: d\,E^2 : p\,E^2,$$

or numerically $-\frac{108}{2} : -36 :: 10^2 : \frac{-36 \times 10^2}{-54} = p\,E^2$.

Hence $p\,E = 20\sqrt{\frac{1}{6}} = 8{\cdot}15$; and consequently

$$A\,p = AE - p\,E = 69 - 8{\cdot}15 = 60{\cdot}85.$$

Let us now take the moments of the triangle ABC, and the trapezium CDP p = △ CDE − △ P p E, with respect to the line P p, in which case we shall, in the first place, have for the portions of the centres of gravity

$$\begin{aligned}
p\,b &= A\,p - A\,b = 60{\cdot}85 - 16{\cdot}3 = 44{\cdot}55\\
p\,d &= d\,E - p\,E = 10 - 8{\cdot}15 = 1{\cdot}85\\
\tfrac{1}{3}\,p\,E &= \tfrac{8{\cdot}15}{3} = 2{\cdot}72;
\end{aligned}$$

and secondly, for the moments required, the following results:

distance of $\frac{3}{5}$ of the depth from the vertex, (Vince's *Fluxions*, p. 101,) and the centre of oscillation at $\frac{5}{7}$, when the point of suspension is at the vertex (p. 111,) the distance of these points $\frac{4}{35}$ will be increased to $\frac{6}{35}$, when the point of suspension is removed to the terminaton of the absciss, and the distance of the centre of pressure from the vertex will be $\frac{3}{5} - \frac{6}{35} = \frac{3}{7}$, and $\frac{3}{7} \times 18.84 = 8.074$ which, subtracted from $\frac{4}{9} \times 40 = 17.777$, leaves 9.703 for the length of the lever. Now the magnitude of the pressure on this section must be to 3000 tons, as the depth of the centre of gravity, 7.536 to 176, that is 128.45 tons, which, acting at the distance 9.703, will produce a strain of 1247 tons, or, in the terms of the preceding calculation .1247, which is the multiple of $\frac{1}{2}\,x^2$ indicating the fall. These different causes of arching being independent of each other in their operation, their effects will be simply united into a common result; and the whole curvature of the ship, supposing its strength equable throughout its length, may be thus represented:—

Distance from the stern -	0	22	44	66	88	110	132	154	176
Strain - - - -	1247 + 0	605	1993	2815	2224	2655	4610	1875	0
Fall - - - -	.04828	.02716	.01207	.00302	.00000	.00302	.01207	.02716	.04828
	.08697	.05325	.02514	.00552	.00000	.00507	.02531	.06705	.12325
	.13525	.08041	.03721	.00854	.00000	.00809	.03738	.09421	.17153
For twelve inches of arching	10.58	6.29	2.91	.67	.00	.63	2.93	.737	13.42

$$44.55 \times +\ 72 = +\ 3207.6$$
$$1.85 \times -\ 108 = \quad -\ 199.8$$
$$2.72 \times -\ 36 = \quad -\ 97.8$$

and since the value of the positive moment is $+3207.6$, and the aggregate of the negative moments -297.6, the definitive moment will be $+3207.6 - 297.6 = 2910$: a positive quantity, whose tendency is to make the stern of the vessel fall.

If, however, in conformity to the second theorem, we find that the moment of the infinitely small section contiguous to the plane of the moments here referred to, be of a contrary character to that of the definitive moment just deduced, we shall be justified in concluding, that the moment of 2910 is absolutely the greatest that can be discovered; and that the moment of the infinitely small section alluded to, is *negative*, is apparent on account of its partaking of the general condition of the triangle CDE, which has all its sections of a *less* weight than the volumes of water they respectively displace, whereas the total moment by the preceding calculation is clearly *positive*.

If, in the next place, we proceed to the consideration of the sections comprised between the points E and G, and remark, that by the primitive hypothesis, the area of the triangle $EFG = +118$, which is a quantity greater than the area of the triangle $E\,p\,P$; let us suppose a line $Q\,g$ to be so drawn, perpendicular to the water's surface, as to cut off the triangle $Q\,g\,E$ equal to the triangle $E\,p\,P$. To determine the position of this line, we have, by the similar triangles $F\,f\,E$, $Q\,g\,E$, the proportion,

$$\text{as } \triangle F\,f\,E : \triangle Q\,g\,E :: E\,f^2 : E\,g^2,$$

$$\text{or numerically } \frac{118}{2} : 36 :: 25^2 : \frac{36 \times 25^2}{59} = E\,g^2$$

Hence $E\,g = 150\sqrt{\frac{1}{59}} = 19{\cdot}5$, and consequently

$$A\,g = AE + E\,g = 69 + 19{\cdot}5 = 88{\cdot}5.$$

Taking therefore, the moments of the triangles ABC, CDE, and $Q\,g\,E$, with respect to the line $Q\,g$, in which case we shall, in the first place, have for the positions of the centres of gravity

$$g\,b = A\,g - A\,b = 88{\cdot}5 - 16{\cdot}3 = 72{\cdot}2$$
$$d\,g = A\,g - A\,d = 88{\cdot}5 - 59 \quad = 29.5$$
$$\frac{1}{3}E\,g \qquad = \frac{19{\cdot}5}{3} \qquad = 6{\cdot}5$$

and secondly, for the moments required,

$$72{\cdot}2 \times +\ 72 = +\ 5196$$
$$29{\cdot}5 \times -\ 108 = \quad -\ 3186$$
$$6{\cdot}5 \times +\ 36 = +\ 234$$

and, since the values of the positive moments amount to $+5430$, and the negative moment is -3186, the definitive moment will be $5430 - 3186 = 2244$, a positive quantity.

If now we consider the nature of the sections which are infinitely near to $Q\,g$, we shall perceive that their weights exceed their displacements, and that their tendency is to produce a curve in the ship analogous to the moment just determined; and that therefore the moments which tend to arch the ship longitudinally in $Q\,g$, at the distance of 88·5 feet aft, must, by Theorem III. be a *minimum*.

Let us now proceed to the consideration of the sections which are situated between the points H and M. The displacements of these sections, as we have before remarked, exceed their absolute weights, by a quantity equivalent to $-119 + 155$; and which quantity is greater than the total result $+72 - 108 + 118$, on account of the other differences before referred to. It is evident, therefore, that we may cut off from the triangle HIM, by means of the vertical line $B\,r$, such a triangle $HR\,r$ as to make

$$ABC + EFG - GDE - HR\,r = o.$$

and which condition furnishes for the value of the area of the triangle sought,

$$HR\,r = ABC + EFG - CDE$$
$$= 72 + 118 - 108$$
$$= 82.$$

Hence we shall have by proportion, as

$$\triangle HIK : \triangle HR\,r :: HK^2 : H\,r^2,$$

$$\text{or numerically } 119 : 82 :: 13.4^2 : \frac{82 \times 13.4^2}{119} = H\,r^2;$$

$$\text{whence } H\,r = 13.4\sqrt{\frac{82}{119}} = 11.21,$$

and consequently $A\,r = AH + H\,r = 125.6 + 11.21 = 136.81$.

Taking now the moments of the triangles ABC, CDE, EFG, and $H\,r$ R in relation to the line R r, we shall, in the first place, have for the positions of the centres of gravity,

$$r\,b = r\,A - A\,b = 136.81 - 16.3 = 120.51$$
$$r\,d = r\,A - A\,d = 136.81 - \ 59 \ = \ 77.81$$
$$r\,f = r\,A - A\,f = 136.81 - \ 94 \ = \ 42.81$$
$$\tfrac{1}{3}\,r\,H \qquad = \frac{11.21}{3} \qquad = \ 3.74$$

and, secondly, for the moments required

$$120.51 \times +\ 72 = +\ 8676.72$$
$$77.81 \times -\ 108 = \quad -8403.48$$
$$42.81 \times +\ 118 = +\ 5051.58$$
$$3.74 \times -\ 82 = \quad -306.68$$

and since the values of the positive moments amount to 13728.30, and of the negative moments 8710.16, it follows that the definitive moment will be the positive quantity 5018.14

Here, therefore, as in the vertical plane passing through $P\,p$, the sections which are infinitely near to R r, will have their weights less than the resistance of the water they displace; and the moments of the same sections act in a contrary direction to that of the total moment. Hence, by the second theorem, the positive moment 5018.14, above deduced, is a *maximum*.

At the extremities A and O of the vessel, the sum of the moments being zero, must furnish likewise two *minimum* values; and if we therefore collect together the series of *maximum* and *minimum* values of the moments having a tendency to arch the vessel, they may be represented as in the following table:

At zero or the point A.	At A p = 60·85 feet from A.	At A q = 88·53 feet from A.	At A r = 136·81 feet from A.	At A o = 176 feet from A.
Minimum.	Maximum.	Minimum.	Maximum.	Minimum.
Value of the moment = 0.	Value of the moment = 2910.	Value of the moment = 2244.	Value of the moment = 5018·14.	Value of the moment = 0.

According to Dr. Young, (see the preceding note,) the moments estimated at every 22 feet from the stern to the stem, may be represented as in the following table:

At zero.	*At 22 ft.*	*At 44 ft.*	*At 66 ft.*	*At 88 ft.*	*At 110 ft.*	*At 132 ft*	*At 154 ft.*	*At 176 ft*
Value of the moment = 0	Value of the moment = [illegible]05	Value of the moment = 1943	Value of the moment = [illegible]515	Value of the moment = [illegible]	Value of the moment = [illegible]	Value of the moment = [illegible]	Value of the moment = [illegible]	Value of the moment = 0*

If we now refer to the maximum and minimum sections which pass through A p and A q, in the investigation of Dupin, we shall perceive, that from the former to the latter, there must be a continual declension in the value of each moment; and that consequently, at the distance of 88 feet from the origin at A, the magnitude of the moment must be greater, than at the distance of 82.53 feet from the same point where the maximum section obtains; a conclusion which agrees with the theory of Dr. Young. In like manner, by referring to the maximum sections deduced by Dupin, we shall find that they are greater than the sections nearest to them in the investigation of Dr. Young.

But the same correspondence in the results does not take place, if we compare the position of the maximum section of Dr. Young with the deductions of Dupin; since the former makes that section to exist at the distance of 111.3 feet from the after part of the water line, and producing a strain equivalent to 5234 tons, acting at the distance of one foot; whereas the last mentioned philosopher estimates the strain at a similar point to be 4020.3 tons. This subject therefore, like most others connected with naval architecture, requires a more rigorous and extended investigation; and we regret that our limits prevent us from entering farther into so interesting an inquiry at the present time.

The preceding investigation has been conducted on the supposition, that the causes of arching are due entirely to the unequal distribution of the weight and pressure; but there is, in fact another cause for this important derangement of a ship's figure, arising from the longitudinal and horizontal pressure of the water. According to Dr. Young, the partial pressure of the water in a longitudinal direction, affects the *lower* part of the ship only, compressing and shortening the keel, while it has no immediate action on the upper decks.† The pressure, thus applied, must obviously occasion a curvature, if the angles made with the decks by the timbers, are supposed to remain unaltered, while the keel is shortened, in the same manner as any soft and thick substance, pressed at one edge between the fingers, will become concave at the part compressed; and this strain, upon the most probable supposition respecting the comparative strength of the upper and lower parts of the ship, must amount, Dr. Young thinks, to more than one third as much as the mean value of the former, being equivalent to the effect of a weight of about 1700 tons, acting on a lever of one foot in length, while the strain, arising from the unequal distribution of the weight and the displacement, amounts, where it is greatest, that is, about 87 feet from the head, to 5234, in a seventy-four gun ship of the usual dimensions; and although the strain is considerably less than this exactly in the middle, and throughout the aftermost half of the length, it is nowhere converted into a tendency to "sag," or to become concave. It must, however, be remembered, says Dr. Young, that when arching actually takes place from the operation of these forces, it depends upon the comparative strength of the different parts of the ship and their fastenings, whether the curvature shall vary more or less from the form, which results from the supposition of a uniform resistance throughout the length. An apparent deviation may also arise from the unequal distribution of the weight through the ship; thus the keel may actually sag, under the step of the mainmast, even when the strain, as here calculated, indicates a contrary tendency with respect the curvature of the whole ship.

But the magnitude of the strain on the different parts of a ship is subjected to very material alterations, when she is exposed to the force of the wind and waves. The effect of the wind is generally compensated by a change of the situation of the actual water

* As every addition to our knowledge on the important subject of arching is valuable, and as some of our readers may be desirous of pursuing it farther than the limits of this article will allow, we annex the following elements of the weights and vertical pressures on a ship of 74 guns of the second class, and which we have derived from a very useful and instructive work, entitled, *An Introductory Outline of the Practice of Shipbuilding*, by Mr. Fincham, superintendent of the School of Naval Architecture in Portsmouth Dockyard.

† Philosophical Transactions for 1814, p. 308.

line, so that its amount may be estimated from the temporary or permanent inclination of the ship; and the force of the waves may be more directly calculated from their height and breadth. These two forces can seldom be so applied, as to combine their effects, in producing a strain of the same kind in their full extent; it will therefore be sufficient for this purpose, to determine the probable amount of the force of the waves, which is more materially concerned in affecting the longitudinal curvature than that of the wind. As a fair specimen of the greatest strain that is likely to arise from this cause in any common circumstances, we may consider the case of a series of waves twenty feet in height, and seventy in breadth; the form being such, that the curvature of the surface may be nearly proportional to the elevation or depression. A single wave might indeed act more powerfully than a continued series, but such a wave can scarcely ever occur singly. Dr. Young then finds,* that the greatest strain takes place, in a seventy-four gun ship, at the distance of about eighteen feet from the midships, amounting to about 10,000 tons, at the instant when the ship is in a horizontal position, while, in common cases, when the waves are narrower, the strain will be proportionally smaller and nearer to the extremity. Hence it appears that the strain produced by the action of the waves, may very considerably exceed in magnitude, the more permanent forces derived from the ordinary distribution of the weight and pressure; being according to this statement, nearly three times as great: so that when both strains co-operate, their sum may be equivalent to about 15,000 tons, acting on a lever of one foot, and their difference, in opposite circumstances, to about 5000. There may possibly be cases in which the pressure of the waves produces a still greater effect than this; it may also be observed, that the agitation accompanying it, tends to make the fastenings give way much more readily than they would do, if an equal force were applied less abruptly. At the same time, it is not probable that this strain ever becomes so great, as to make the former perfectly inconsiderable in comparison with it, especially if we take into account the uninterrupted continuance of its action; it appears, therefore, to be highly proper, that the provision made for counteracting the causes of arching, should be greater than for obviating the strain in the contrary direction; for example, that if the pieces of timber intended for opposing them were, on account of the nature of their fastenings, or for any other reason, more capable of resisting compression than extension, they should be so placed as to act as *shores* rather than as *ties*; although it by no means follows, from the form which the ship assumes after once breaking, that the injury has been occasioned in the first instance, by the immediate causes of arching; since, when the fastenings have been loosened by a force of any kind, the ship will naturally give way to the more permanent pressure, which continues to act on her in the state of weakness thus superinduced.

The pressure of the water against the sides of a ship, has also a tendency, remarks Dr. Young, to produce a curvature in a *transverse direction*, which is greatly increased by the distribution of the weights, the parts near the sides being the heaviest, while the greatest vertical pressure of the water is near the keel. This pressure is often transmitted by the stanchions to the beams, so that they are forced upwards in the middle: when they are unsupported, the beams are more generally depressed in the middle by the weight of the load which they sustain, while the inequality of the pressure of the water co-operates with other causes in promoting the separation of the sides of the ship from the beams of the upper decks. On the other hand the weight of the mainmast often prevails partially over that of the sides, so that the keel is forced rather downwards than upwards in the immediate neighbourhood of the mid-ships. The tendency to a transverse curvature is observable, when a ship rests on her side, in the opening of the joints of the planks aloft, and in their becoming tighter below: although this effect depends less immediately on the absolute extension and compression of the neighbouring parts, than on the alteration of the curvature of the timbers in consequence of the pressure.

In such a case also there is an obvious strain tending to produce a *lateral curvature*, and shores are sometimes employed to prevent its effects, when a ship is "*hove down*" on her side. This indeed is comparatively a rare occurrence; but when a series of large waves strikes a ship obliquely, they must often act in a similar manner with immense force: the elevation on one side may be precisely opposite to the depression on the other; and the strain from this cause can scarcely be less than the vertical strain already calculated: but its effects are less commonly observed, because we have not the same means of ascertaining the weakness which results from it, by the operation of a permanent cause. When a ship possesses a certain degree of flexibility, she may in some measure elude the violence of this force, by giving way a little for the short interval occupied by the passage of the wave; but it may be suspected that her sailing in a rough sea, must be impaired by such a temporary change of form.

Such are a few of the general principles connected with that alteration of form, which has been denominated arching or hogging, and for which the genius of Seppings contrived so admirable a remedy. The symptoms of weakness which all ships constructed on the old plan exhibited, were generally apparent, by the parting of some of the butts of the plank aloft, at the same time that the angular position of some parts of the structure had as uniformly been more or less altered; and very generally a certain degree of sliding was observable in the planks at the side of some of the ports. At the same time, a degree of permanent compression or crippling below was remarked, the butts of the planks opening when the cause that produced the arching had been removed, and the sheathing more wrinkled than would have happened from the simple bending of the planks. But as the practical details connected with the introduction of the diagonal riders, belong more particularly to the part of the paper devoted to practical construction, we refer the reader to it for further information.

ON THE STERNS OF SHIPS.

The interesting and important investigations, that have taken place respecting the sterns of our ships of

* Philosophical Transactions for 1814, pages 310 and 311.

war, not having yet found their way into any of our Encyclopædias, we shall devote a short space to its consideration, and review the arguments that have been advanced by different writers respecting this great and important change.

It would exceed our limits to follow the history of the sterns of vessels into its earliest stages, and we must therefore content ourselves with briefly remarking, that during the sixteenth century, the sterns of ships of the largest class were formed square, not only above, but some feet *below* the plane of flotation; and every part was loaded, or as the writers of that period say "adorned," with carved work, banners, and every other thing that could add to what was at that time considered as rich and splendid decoration. The forms of the sterns at that time, admitted of four guns, of large calibre, being fired right aft; and we learn from a picture preserved in the society of antiquaries, of the embarkation of King Henry the VIII. at Dover, in the year 1520, that ships at that period, had neither stern walks, balconies, nor quarter galleries; nor is there represented the convenience of a water closet abaft, even in the ship occupied by his Majesty; and but one only in the squadron, which is in a ship bearing the royal standard; and which, it is evident from the colouring, was an appendage for the occasion, and probably put up for the queen of England and her court. The sterns of these ships, Mr. Knowles thinks, were formed by several beams of considerable dimensions, called transoms, lying horizontally, and attached to their frames or ribs, by large crooked pieces of timber, termed knees, and which, it would seem, prevented the guns from being worked in the quarters with any effect.

In the beginning of the seventeenth century, our ships of war were much improved, not only by an increase of their dimensions, but also by the application of science to the construction of their bodies; and Sir Robert Seppings is in possession of a complete draught of the Sovereign, designed by Mr. Phineas Pett, and launched in the year 1637, in which the stern is improved by being *rounded below* and a little above the plane of flotation; and having five transoms and stern and quarter galleries, or balconies. Her draught of water abaft was twenty-two feet three inches, and the height of the stern above the water *fifty feet nine inches*, and she had originally *six decks or platforms abaft*, on which guns might be carried. But not only the sterns of ships, but their heads also were overloaded with the most barbarous and cumbrous ornaments at this time; and the prow of the ship here alluded to, actually extended forty-three feet six inches above the plane of flotation, and was covered in every part with massive and ill-contrived carved work.*

This cumbrous and expensive mode of building and ornamenting the heads and sterns of ships of the first class, continued, says Mr Knowles, until the year 1699, when directions were given by the government, "to be more sparing in the carved work and other decorations"—a proof of a better and improving taste. The balconies in the quarters were however fitted until the year 1729, when these projections were discontinued, and close galleries adopted.

To lower the height and lessen the weight of the sterns in large ships, the poops royal were omitted in those built and repaired after the middle of the last century: but little however appears to have been done in the way of a decided improvement until 1796, when Earl Spencer, who then presided at the Admiralty, directed that the ponderous heads should no longer be continued, nor should there be galleries or carved work on the sterns. This was certainly a step towards a more proper order of things: but it was not until 1811, that Sir Robert Seppings introduced his method for strengthening the bow, by carrying up the timbers so as to give a circular form to it: nor till 1816, that he proposed that the same system should be adopted for the stern, so as to give to it the same advantageous properties that he had previously communicated to the bow.

The advantages to be derived from the circular stern may be principally reduced to the three following heads:

First, A considerable addition to the strength of the ship.

Secondly, Safety to the people employed, both from the effects of a sea striking the stern, and from shot fired by the enemy.

Thirdly, The additional means afforded for attack and defence.

The insufficiency in point of strength of the old method of constructiong the sterns, is proved in Sir Robert Seppings's letter to the first Lord of the Admiralty, by his having given from various official reports, eighty-nine instances in ships of the line, and eighty in frigates, of the great weakness of that part of the ship. These instances of defect being derived from the reports of officers of intelligence and distinction, employed in services of the most diversified and trying kind for the long period of a quarter of a century,† necessarily stamps the body of information

* It is remarkable how this rage for ornament, falsely so called, prevailed at one time, and how low it degraded the national taste. Let the reader compare, in this particular, the cumbrous and overloaded light-house of Winstanley, with the simple and majestic structure afterwards built on the same rock by the immortal Smeaton.

† It may not be uninteresting to our readers to have a few examples of the weakness of the old form of the stern presented to their notice.

In the report relating to the Valiant, it is stated, *that the stern post, and all the stern, worked.* In the Diadem, *the after part of the ship sunk so much, as to cause a considerable friction of the rother against the post.* In the Adamant, *the stern frame was so very much depressed, that the stern timbers were nearly out of their steps on the wing transom* In the Courageux, *the working of the stern frame was so great in a heavy gale of wind, as to occasion the loss of five tillers;* and on the storm assuming afterwards a still more tremendous character, *the working about the stern frame and post was so great, as to render it necessary to throw twelve of her after guns over-board, to ease and lighten her.* And in a similar scene of peril, in which the Albion was situated in 1809, *thirty-one guns were thrown overboard, twenty-four of which were from the after extremity of the ship.* Nor is it always necessary for a gale of wind to exist, in order to prove the weakness of the square stern, since, in the example of the Defence, *the heads of her counter timbers were reported by her Captain to work very much even in moderate weather.* And the stern of the London *was found to tremble much in light winds, and to increase its motion considerably in heavy seas.* In the Aquilon also, *the stern frame was found to be much shook by firing the after guns.* The poop of the Bellona *was found likewise to labour so much as to work the foremost bulkhead partly down;* and when the Minotaur rolled, *the whole body of the poop went over from side to side.* The stern of the Cumberland also, above the wing transom *worked so* which Sir Robert has collected in the letter alluded to, with the utmost importance and value. The defect in the old square form being thus rendered so notorious, led to the consideration of the best mode of remedying it; and the acknowledged strength of the round bow, a part subjected to the action of far greater strains than the stern, naturally led to the consideration of fortifying the latter by the same mode of timbering, and from this arose the circular stern. Moreover, before the application of this system, the new mode of shipbuilding so successfully introduced by Sir Robert Seppings, might be truly said to be incomplete, for the shelf pieces and water ways, as well as all the planking above the wing transom, which may be denominated internal and external hoops, were cut off, and hence left the stern the only weak part in the ship. "In ships with square sterns," Mr. Harvey has remarked, "the application of the diagonal system of trusses does not produce its maximum effect, nor is the continuity of the shelf pieces preserved, since the most abrupt termination of them takes place at the quarters, a difficulty entirely removed in the circular form by the happy introduction of the *ekings*, and affording a perfect illustration of the term 'internal hoop,' so appropriately applied to them by Sir Robert Seppings." "It is the mode of timbering those sterns," as Mr. Knowles with equal propriety observes, "and a continuity of the internal and external planking that constitute their strength, and establishes on a firm and unquestionable basis, their importance and value."

These remarks will be confirmed by an inspection of Figs. 1, 2, 3, and 4. Plate CCCCXCVI. In Figs. 1 and 3, the former of which represents an internal right aft view of a square stern, and the latter a plan representing the mode of connecting a stern of the same kind, with its sides, it will be perceived that the strength of this form of the stern depends in a very great measure on the iron knees at the quarters or angles, which are bolted to the deck transom A, and through the side timbers of the vessel. Now any fracture or defect in the iron knee, will of course weaken the stern, and contribute to all the defects before alluded to, and which have led to the introduction of the new form. It will also be perceived by inspecting both figures, but particularly the former, that none of the water ways C, C, C, C, or shelf pieces D, D, D, D, contribute in any degree to bind together the fabric of the stern, or to add in any manner to its strength: nor do any parts of the stern frame, excepting the transoms, tend to keep the sides of the ship together, and which is only done by means of the iron knees before alluded to, and the dowels, denoted by the dotted circles at their extremities. On the wing transom F, moreover, rests the whole fabric of the stern, every upright timber as B, B . . . B, B, stepping or resting thereon. Now, we will venture to say, that in the whole history of constructive carpentry, a worse example can scarcely be found than this of defective and bad combination; of timbers disposed at right angles to each other,—the worst possible position, where oblique strains are to be endured; without a diagonal timber to prevent even the well-known derangement of form arising from *raking:* trusting to knees and bolts, ill adapted, from their positions, to resist those derangements of form which must arise from the shocks that so ponderous a fabric must receive from the terrible element with which it has to contend, and with the decays also and weaknesses that *time*, the great innovator of mechanical as well as moral systems, is so incessantly producing. Can it be a matter of wonder, therefore, that such an ill-contrived frame as the stern of a ship constructed on the old form, should, in the technical but expressive language of the operative shipwright, "*work:*" *that the whole body of the poop should sometimes move from side, to side*, resting, as the entire fabric of the stern does, on a single timber, massy, of course, but with its strength ill applied, and ill connected with the sides of the ship, the proper and perfect union of which should be inseparable?

But if we turn to the diagrams illustrative of the round stern, we shall discover no such mechanical anomalies as disgrace the ancient form. Every part will be found to be disposed with some reference to the laws that ought at all times to influence mechanical structures. To prove this in its fullest sense, we need only compare Fig. 2. with Fig. 1. and Fig. 4. with Fig. 3.

The slightest comparison, indeed, will prove that weakness has given way to strength; and forms ill adapted to resist strains, have been replaced by mechanical arrangements of the soundest kind. The water ways and shelf pieces, which in the square form were abruptly cut off, in the circular stern are bound into one perfect whole, by the introduction of the eking. This ingenious arrangement may be seen in Figs. 2. and 4. where H, H represent the water ways, I, I the shelf pieces, and G, G the timbers denominated the *ekings*, the whole being bound by the solid timbering of the stern, into one compact and perfect form. The stern, it will also be perceived by a reference to Fig. 4. possesses the same kind of timbering, planking, &c. as the sides: the ekings are united by the strongest bolts, and the archlike fabric of the whole is just that which is best adapted to resist strains and pressures of every kind. If we compare Fig. 2. with Fig. 1. we shall find the timber work of the former, raised regularly from the lowest part, resting on no ill-contrived transom; with no stern timbers raising their upright forms, unchecked by brace or truss; but the whole system of framing, adapted to approved rules of mechanical strength, bound together by internal and external planking like the sides, and capable, like the bow, of resisting all those terrible shocks, to which a vessel exposed to the uncontrolled energies of a storm must be subject.

In the second place, the safety which the present

much as to force the oakum out of the butts of the lower counters, at the rabbet of the stern post, as likewise out of the seams of the lower counters.

"Such are a few of the striking examples," says Mr. Harvey, "in one of his Essays on Circular Sterns, (*Dr. Brewster's Journal of Science*, vol. i. p. [illegible]), on which Sir Robert Seppings grounds his arguments for a change in the figure of the stern; facts which had been silently accumulating for a long period in the records of the navy office, awaiting the hand of a '*master*,' to draw from them incontrovertible proofs of the general weakness of the square form, and at the same time to afford the elements and [illegible] of a new system which has contributed in no inconsiderable degree to the strength and security of our ships of war."

method of constructing the sterns affords to the seamen over that of the old plan, is best shown by some instances of the danger arising from the imperfections of the latter method, which, above the wing transom presented little else then a surface of glazed windows. The Dictator of 64 guns, in her passage from the West Indies in 1797, was struck by the sea on the stern, which stove in the dead-lights and window frames, washed away every thing on the main deck, and the crew were under the necessity of throwing six of the guns overboard to lighten the ship abaft. The Revolutionaire, of 45 guns, on her passage also from the West Indies in the year 1804, met with a similar accident, which stove in the dead-lights, and carried away the bulk-head of the great cabin, and had not the hatchways been barred down, which prevented the water from getting into the hold, the ship must have foundered.

In the sterns formed according to the old plan, the men on all the decks, except those on the lower gun-deck in ships of the line, are exposed to the most destructive raking fire, their sterns being pervious even to a musket ball.

The strength also given to the circular sterns by carrying up the timbers, prevents all the danger to be apprehended from a sea striking the ship abaft, or from the ingress of small shot, as well as from large ones which have not force to pass through the timbers and planking. And from their curved form, the shocks of the sea abaft will be much lessened; and those shot fired at an angle of more than forty-five degrees, will glance off without doing much injury to the ship.

Much has been said with respect to the injury which our men-of-war will undergo in their sailing qualities by the introduction of the circular stern; but we apprehend, that an impartial examination of the question will produce some advantages in its favour. The ships constructed with the new stern have the same form below, and for some feet above the plane of the water's surface, and must therefore enjoy the same buoyancy abaft, as those constructed according to the strictest letter of the old plan. Their seagoing properties are no doubt improved by the omission of the quarter galleries, which doubtless acted as a back sail, when the ships were going on a wind.

On the important question of the additional means of attack and defence afforded by the curvilineal stern, we cannot do better than follow Mr. Harvey in his elaborate "Results of Experiments relating to the comparative means of defence afforded by ships of war having square and curvilineal sterns," published in the 35th Number of Mr. Brande's Journal of Science.

For the purpose of ascertaining, by rigorous and decisive experiments, in what degree the new form of the stern is calculated to improve a ship, Mr. Harvey was permitted by Sir Byam Martin, the comptroller of the navy, to select two frigates of the same class, one having a curvilineal stern, and the other one of the old or square form. In the prosecution of the experiments, moreover, Mr. Harvey was assisted by many distinguished naval officers, among whom he particularly mentions Captains Wise, Richards, and Arthur. Guns were placed on board the Boadicea and Hamadryad frigates, the former having a square stern, and the latter a round stern; and he remarks, that every position and bearing determined, was made the subject of a candid and liberal discussion. In determining also the different bearings of the guns, particular care was taken in every instance to prevent their being *wooded*; an important consideration in a course of comparative experiments of this nature; and also ample room was permitted for recoil. The moment also the position of a gun was finally determined, its bearing was carefully laid down on the deck, and referred to a longitudinal line passing through the middle section of the ship. And, in order to give every possible advantage to the square stern, *the ports of the Boadicea were entirely stripped of their linings, so as to present only the naked timbers; whereas in the ship with the curvilineal stern, the linings were in every case preserved*, and which, therefore, gave to the square form, a very considerable advantage during the comparison; but even with this advantage, Mr. Harvey found that the means of defence it afforded, were decidedly inferior to those presented by the curvilineal form.

For the purpose of comparing the different bearings of the guns, two points K, K, Figs. 1 and 2, Plate CCCCXCVII. were assumed in the longitudinal axis XY of the vessels, at the distance of 17 feet from the afterpart of the counter of the square stern, and also from the afterpart of the lower stool of the curvilineal stern. From these points as centres, and with radii of 27 feet, two arcs of circles *a b c e b a*, *a b e f f e b a* were described, the former, as the figure indicates, surrounding the square stern, and the latter that of the curvilineal form. To these circumferences, the various arcs or ranges swept over by the guns, in their translation from one bearing to another, were in all cases referred.

The first experiments were performed on board the square stern vessel. An eighteen pounder was placed at the after broadside port, and trained to its greatest possible angle *before* the beam, as denoted by the lines A *a*, Fig. 1, or Fig. 3, Plate CCCCXCVII.; forming, in the first mentioned figure, an angle *a* AY of 61°, with the principal longitudinal axis XY of the vessel; the outer extremity of the muzzle of the gun being at the same time within the external edge of the port four inches. This bearing being determined, the gun was next brought into the position denoted by the line B *b*, Fig. 1, being the greatest possible angle at which it could be trained *abaft* the beam; the line of fire forming with the principal axis of the vessel the angle *b* BX of 35½°. The arc *a b*, intercepted between the two bearings, amounted to 46°; and it hence followed, that an object placed in any part of it could be hit by a shot from the after broadside port, confined of course to the limits prescribed by the ordinary charge of powder. The circular dots introduced in the arc *a b*, as also in all the arcs which may be hereafter alluded to, are designed by Mr. Harvey to indicate, that every part of the space contained between the extreme bearings, can be perfectly defended.

The exact position of the point *b* having been determined by the last experiment, the gun was next removed to the adjacent port of the stern, and trained to its greatest possible angle, as denoted by the line C *c*, Fig. 1, or Fig. 4, and forming with the axis XY the angle *c* CX of 32½°. To obtain this bearing, the muzzle was brought 4 feet *within* the fore part of the rail, creating thereby great danger from fire. It will also be observed, by referring to the former figure, that the truck of the gun was brought into immediate contact with the rudder head, so that the utmost bearing was determined.

This being the greatest bearing that could be obtained with a stern gun directed towards the adjacent quarter of the ship, necessarily left the arc *b c*, Fig. 1, amounting to 32½°, *entirely undefended:* and it was also remarked, that the bearings B *b* and C *c* were not in directions *parallel* to each other, but in a state of *divergency*, amounting to three degrees: and that therefore the extreme lines of fire proceeding from the after broadside port, and the adjacent port in the stern, could not, under the present circumstances, be made to "*cross*," and consequently, that a "*point of impunity*" existed.

Desirous, however, of discovering if it would be possible, under any circumstances, consistently with the preservation of the frame of the ship, to make the lines of fire issuing from the last-mentioned ports *intersect* each other, an estimate was made by Mr. Harvey and the naval officers present, to determine what alteration would be produced in the bearing of the gun at the stern port, by supposing the rudder head removed. The utmost effect, however, that could be produced by this arrangement in the bearing of the gun, amounted only to a diminution of a degree and a half of the divergence before determined, the new line of fire being the direction E *e*, and which, therefore, still kept the bearings of the two guns from a state of *parallelism*, and consequently preserved a "point of impunity" between them.

The undefended arc *b c* was of course diminished by the same quantity as the divergence of the stern gun was altered, the arc *b e* in this new condition amounting to thirty-one degrees. And hence it appears that the lines of fire proceeding from the after broadside port, and the adjacent port in the stern, cannot be made to cross even when the rudder-head is removed, unless by destroying one of the sides of the former port, or a port of the stern frame; and that *a point of impunity therefore exists on the quarter of a square stern vessel, which it is impossible altogether to remove, unless by injuring very materially the strength of the ship.*

The next position assumed for the gun was that of D *d*, Fig. 1, Plate CCCCXCVII, forming with the principal axis XY, the angle *d* DY of 27°, this direction affording the greatest possible bearing at the stern, towards the opposite quarter of the ship, when the recoil was limited to four feet.* The magnitude of the arc *c d*, between the extreme bearings at the stern port, was therefore found to be 30½° when the rudder-head was preserved, but nearly a degree more when it was removed.

From the foregoing experiments, it therefore appears that the entire arc *a b d b a* surrounding the square stern, and which amounts in quantity to 204°, may be separated into the

three defended arcs $\begin{cases} a\,b = 46° \\ c\,c = 47° \\ a\,b = 46° \end{cases}$

amounting together to 139°: and into the

two undefended arcs $\begin{cases} b\,c = 32\tfrac{1}{2}° \\ b\,c = 32\tfrac{1}{2}° \end{cases}$

amounting jointly to 65°.

Of the defended arcs, it may be observed, that the first and last *a b*, *a b*, admit of a ready defence in any part from either of the after broadside ports: but the second, or right aft portion *c c*, cannot be defended in every part from the stern ports with the same convenience and security from fire.

For the purpose of affording a more explicit reference to the different bearings of the guns above referred to, the following table is added, of which the first column denotes the several angles formed by the lines of fire with the principal axis of the ship: and the second, the distances of the points of intersection formed by the respective lines of fire and the same axis, reckoned from the point K, the centre of the arc surrounding the stern.

Magnitudes of the angles formed by the respective lines of fire and the axis XY.	Distances of the points of intersection of the lines of fire with the axis XY, reckoned from the common origin K.
a AY = 61°	KA = 9.0 feet.
b BX = 35½°	KB = 16.7
c CX = 32½°	KC = 8.5
d DY = 27°	KD = 20.5

Having considered the effects capable of being produced by guns applied *singly*, let us next follow Mr. Harvey into an investigation of their joint action.

Suppose, therefore, in the first place, a square stern vessel to be attacked at the same instant, both on the stern and starboard quarters. It is evident that it would not be possible to fight the after broadside gun directly a-beam, and the adjacent stern gun right aft, at the *same time*, since the distance between the trains of the carriages, when completely run out, would only amount to fifty inches; and which, when the recoil takes place, would necessarily bring them into contact with each other. One of three things must therefore be done in a case of such a nature: either the former gun must be trained abaft the beam, the fire of the latter be brought nearer to the quarter of the ship attacked, or the latter gun be removed and fought at the other stern port. It might be possible also to fight both the after broadside guns by training them abaft the beam, with both the stern guns trained right aft: but, as before shown, *under no circumstances can the lines of fire be made to cross each other on the quarters of the ship, a point so much to be desired on so many difficult and trying occasions.*

The utmost advantage indeed that can be obtained from crossing the lines of fire, must in strictness be limited to a single combination produced by the stern guns immediately abaft, and confined to the space between the lines of extreme fire *d*D*k*, *d*D*k*, Fig. 1, Plate CCCCXCVII. It is true, by forming new lines of bearings for the guns, within the limits here referred to, an indefinite number of intersecting points may be created; still it is obvious that *one* only can be obtained at the *same* time. For example, a point of cross fire may be found at D, produced by the extreme lines of fire; or by gradually approximating those bearings to each other, other points in the axis XY may be determined, more distant from the stern, thereby commanding the sectorial space D*gg*. So also, other points may be found, out of the principal axis, by corresponding bearings of the guns. Thus

* In such an application of a gun, the breeching must be so ordered as to prevent a greater recoil.

the points gg may be determined, by combining either of the right aft lines of fire I*i*, I*i*, with one of the extreme lines of fire *d*D, *d*D, and sweeping over, by different modifications of these lines of fire, the sectorial spaces *g i k*, *g i k*. In like manner, by varying the bearings of the guns, may any number of points of intersection be determined within the bounds of extreme fire; but only *one*, as before remarked, can be determined at the *same* time. Thus, *the advantage of a cross fire, which in military purposes is always of so much moment and importance, in the case of the square stern, is limited and confined in an extreme degree.*

From the preceding considerations, it therefore appears, that the defence of the square stern is subject to the following disadvantages:

First,—*Two considerable arcs exist on the quarters, incapable of being defended; and hence a point of impunity is created, from the impossibility of crossing the lines of fire, which proceed from the after broadside gun, and either of the stern guns.*

Secondly,—*That to defend even an arc of 47°, right aft, produces much inconvenience, and a considerable waste of time, from the difficulty of obtaining the requisite positions for the guns, in consequence of the rudder head, and the projecting timbers of the stern.*

Thirdly,—*That in defending the arc before mentioned, the dangers of fire are very considerable, from the muzzles of the guns being so very much within the whole of the stern frame.*

Fourthly,—*That only one point of cross fire can be found, at the same time, in any part surrounding the square stern.*

The preceding conclusions having been obtained for the square stern, we shall in the next place proceed to the consideration of the experimental results obtained for the curvilineal stern.*

The first bearing determined in the Hamadryad, was at the after broadside port, an eighteen pounder being trained at the greatest possible angle *before* the beam. The line of fire A*a*, Figs. 2 and 5, Plate CCCCXCVII, so produced, was found to form with the principal axis XY, an angle *a*AY of 53°; the outer extremity of the gun being at the same time coincident with the side of the vessel. From this direction, the gun was trained into that of *b*B, *abaft* the beam, Fig. 2, being likewise the greatest deviation from the line of direct fire the case would admit, without wooding. This line of fire formed with the principal axis XY, an angle *b*BX of 36°; the outer extremity of the muzzle being at the same time two inches within the external edge of the port. The arc *ab* thus swept over by the gun, during its translation from the first-mentioned position to the second, amounted to 48½°, every part of which admitted of a ready and effectual defence.

A gun, in the next experiment, was placed at the port in the adjacent quarter of the ship; the part of the square stern vessel, which was proved in the preceding experiments, to be entirely undefended, but which, in the curvilineal stern, was found capable of making a vigorous defence. To prove this, the first bearing determined, was in the line C*c* *before* the beam, forming with the axis XY, the angle *c*CY of 78°, being the greatest the position would admit, without wooding the gun, or limiting the range of its recoil. From this position, the gun was removed into that of D*d* *abaft* the beam, its direction, Fig. 2, Plate CCCCXCVII, forming with the principal axis, the angle *d*DX of 16½°, the gun having been found capable of sweeping the arc C*d* of 46°, with perfect freedom.

The next situation assumed, was in the adjoining stern port, where the ease with which it was worked afforded a striking contrast to the difficulties experienced in the square form, and called forth the repeated and warm eulogiums of the officers present. Instead of having the projecting timbers of the stern frame, and the rudder head to contend with, in determining the different positions of the guns, as in the experiments performed on the deck of the Boadicea; or the danger of blowing out the entire stern frame,† or of occasioning fire in the vessel, both of which are possible in the case of a vigorous contest, from the muzzle of the gun, when trained right aft, being three feet *within* the stern frame; the gun in the curvilineal stern could be worked, as truly remarked by Captain Wise with all the ease and convenience of one at a broadside port; and that, moreover, when it was trained right aft, its muzzle was found to project considerably *beyond* the stern frame: thus reducing the chances of fire to those of a broadside port whereas in the square stern, they would be increased under similar circumstances, very much beyond them.

The first bearing at the last-mentioned port, was in the direction E*e*, Fig. 2, Plate CCCCXCVII, towards the adjacent quarter of the ship, and forming with the axis XY, an angle *e*EX of 48½°, being the greatest angle from the line of the keel, at which the gun could be trained. The extremity of the gun was an inch within the outer edge of the port; and the di-

* All the bearings hereafter mentioned, were determined with the ports in their ordinary state: no linings having been stripped from them to increase their width, as was done in the experiments on board the Boadicea. It was considered unnecessary in the case of the Hamadryad, because the very superior means of defence afforded by her curvilineal stern, could be most strikingly displayed without removing them. As remarked, however, before, in the text, this difference in the mode of conducting the experiments, gave a considerable advantage to the square stern; but which only served to place in a more striking point of view, the superiority of the new form

† That the blowing out of a square stern is not an hypothetical case, but has in some instances been rendered absolutely necessary, from its imperfect and injudicious form, may be proved by a reference to the gallant action of the Blanche with La Pique, in which the main and mizen masts of the former being shot away, and head sails filling, she payed off before the wind, thus bringing La Pique astern, towing by the bowsprit. The Blanche was immediately much annoyed from her quarter deck guns, which were well served, and pointed forward, without the English frigate being able to return a gun, having *no stern ports* on her main deck. Her gallant commander had no alternative left *but to blow out the stern frame.* To accomplish this, all the firemen, with their buckets, were assembled in the cabin, and both the after guns pointed against the stern, which made a clear breach on both sides, the fire occasioned by the execution of this prompt and judicious plan being immediately extinguished. The La Pique was now raked with great effect, her decks being cleared fore and aft, and soon after she surrendered. An officer remarks, who distinguished himself in this gallant action, that if the expedient of blowing out the stern had not been adopted, the most serious consequences might have been apprehended; at all events, the loss of many men.

rection of the shot passed quite clear of the adjacent water-closet. From this situation the gun was turned towards the opposite quarter of the ship, the line of fire F*f* forming with the axis XY, Fig. 2, Plate CCCCXCVI. the angle *f*FY of 30°, the gun having swept over the arc *ef* of 43°, without the smallest difficulty of any kind. Hence it appears, that the entire range of the arc *af*, from the point *a*, where the limiting fire of the after broadside gun commences, to the point *f*, where the utmost limit of the adjacent stern gun is obtained, is capable of being assailed by an efficient and vigorous fire from either of the ports here alluded to, or from the port in the quarter of the stern: and that, moreover, the weakness of the quarter, which in the square stern has always formed so essential and important an objection, in the curvilineal stern is entirely removed. It may also be added, that when the gun was trained in the last-mentioned position, its muzzle was only an inch without the outer edge of the port. It will likewise be remarked that the line of fire passes entirely clear of the dressing room.

For the purpose of a more convenient reference, the following table is added, the first column of which contains the different angles formed by the lines of fire with the principal axis of the ship: and the second the distances of the points of intersection formed by the same lines of fire with the axis, reckoned from point K, the centre of the circular arc *a b c f f c b a*, which surrounds the stern.

Magnitudes of the angles formed by the respective lines of fire, and the axis XY.	Distances of the points of intersection of the lines of fire with the axis XY, reckoned from the common origin K.
$aAY = 53°$	KA = 10.4 feet.
$bBX = 33$	KB = 18.3
$cCY = 78$	KC = 10.2
$dDX = 16\frac{1}{2}$	KD = 28.2
$eEX = 46\frac{1}{2}$	KE = 8.4
$fFY = 30$	KF = 19.3
$gGY = 65$	KG = 6.2
$hHX = 42\frac{1}{2}$	KH = 3.7
$iIX = 21\frac{1}{4}$	KI = 16.4
$kKX = 90$	K = 0.0
$lLX = 90$	KL = 7.8

Having ascertained the effects capable of being produced by the *separate* actions of the guns, Mr. Harvey next undertook, as in the square stern, the consideration of the advantages likely to result from their combined application.

In the first place, Mr. Harvey remarks, that the points of cross fire are much more numerous than in the case of the square stern, and moreover, that they may be increased *ad libitum*, by varying the bearings of the guns, and which the very convenient form of the stern will permit to be done with so much ease and convenience.

In the next place, Mr. Harvey remarks, that the close approximation of the same points to the parts of the vessel from which the lines of fire issue, is worthy of particular observation. The after broad side port, for example, may be made to cross its fire with the gun into the quarter port at the point *n*, Fig. 2, Plate CCCCXCVII. being little more than two-thirds of a fathom from the side of the vessel; thereby subjecting every part of the sectorial space *n o p*, containing an angle of 66°, and consequently the space beyond it, to the galling action of a cross fire. In like manner, with the stern and quarter guns, it is possible to make the lines of fire intersect each other at *d e*, the distance being less than two fathoms from the quarter of the ship: and therefore exposing every part of the sector *d f s*, whose angle is 41°, and the space beyond it, to the operation of a cross fire, at all distances between the utmost range of the gun, and the point of intersection last alluded to. The close approach of these points to the side and quarter of the vessel, was such as to excite the surprise of all who witnessed the experiment. In a cross fire proceeding from the stern ports, the superiority was equally apparent: the point of intersection F, being found within a fathom of the stern frame, and the sector F *m m* containing an angle of 60°, every part of which was completely commanded.

A more striking example of the advantage which the curvilineal stern affords for producing points of cross fire, may, however, be exemplified, when a ship of this kind is attacked on her quarter. In such a case, the lines of fire proceeding from the after broad side port, and from the adjacent quarter and stern ports, may all be brought to bear on the *same point y*, within less than twelve fathoms of the quarter; the lines of fire being respectively B *y*, H *y*, and E *y*. Fig. 2. Plate CCCCXCVII. In Fig. 2. Plate CCCCXCIX. the guns are represented in the positions necessary to produce this important effect; and where it will be perceived that most ample space is afforded for working them. *Hence it follows, that the quarter, which, in the old form of the stern, was decidedly the weakest part of the ship, in the curvilineal stern possesses the most ample means of defence.*

A like important defence may also be created, supposing it should be necessary at any time to concentrate the lines of fire in some point nearer the principal axis of the vessel: as the point Z for example, Fig. 2. Plate CCCCXCVII. To accomplish this, the guns at both the stern and quarter ports may be employed at the same time, with sufficient space for working them; the lines of fire being D *z*, S *z*, and *f z*, the point where they unite being only twelve fathoms from the stern.

Such are the effects capable of being produced by the extreme bearings of the lines of fire hitherto described; but it is evident that many varieties may be created to meet the diversified circumstances under which ships of war are liable to be placed. In the *first* place, both the stern guns may be evidently fought right aft at the same time, the lines of fire M *m*, M *m*, being in such a case parallel; *secondly*, One of the last mentioned guns may be fought right aft and the other trained to any angle, between the line of fire M *m*, and the limit *f* F; the sectorial figure *m w x*, containing an angle of 30°, produced by the first mentioned bearing, and the limit just alluded to being swept over in such a case. By varying the bearings of these guns, sectorial spaces may be swept over of any magnitude, within the limits of the extreme bearings *f*F, *f*F.

It would be possible, moreover, to fight the guns at the adjacent stern and quarter ports, as indicated by the bearings E i and I i, the lines of fire intersecting in i, and commanding the sector $i\,u\,r$, whose angle amounts to 24°. It is evident also, that by causing the line of fire I i, to approximate towards H h, successive sectors will be created at every new point of intersection. So likewise the bearings of C c and B b may be changed, and an indefinite number of new points determined, between the limits L l and K k. Thus the line of fire C c may be altered into that of L l, commanding in conjunction with the bearing B b, the sector $l\,y\,r$, whose angle amounts to 53°. Or the direction B b may be transformed into any other as K k, intersecting the bearing C c when both are produced.

Any force therefore that may be employed in attacking a ship with a curvilineal stern, will meet with a resistance of a much more formidable kind, than if its energies were expended on a square stern. If we compare, for example, the after broadside ports of a ship of each kind, we shall observe that, in the old form, the insulated fire of a single gun is all the effect that can be produced; whereas in the curvilineal stern, the gun at the quarter port can lend the most effectual aid; and by causing different discharges to converge to the same point, dispense a terrible and destructive cross fire over a very considerable range. And this contrast is increased in a still more remarkable degree, when we compare the conditions of the quarters; since in the new stern, the means of defence, for the same space, are quite equal to those of any other part of the ship, but in the square form vanish altogether. In like manner, if the attacking force were situated directly astern, a much more effectual defence could be created, by means of the former, than could possibly be afforded by the latter, from the great facility it affords in working the guns, and the assistance that may in some cases be obtained from the quarters.

Hence it appears, that even in a greater arc than a semicircle, many points of cross fire be produced about the curvilineal stern: thereby throwing around this important part of a ship the energies of a formidable and perfect defence, and produced by means at once practicable and secure: leaving no point of impunity open to an acute and enterprising enemy, as in the case of the square stern, or any abrupt transition from a well-defended part, to one feeble and insecure.

As a more particular reference may be necessary to the positions of the points of cross fire, the following table has been prepared. The first column indicates the lines of fire which intersect each other: the second column contains the magnitudes of the ordinates representing the distances of the points of cross fire from the principal axis XY; and the third the distance of the ordinates estimated on the principal axis from the common point of origin K. To refer for example the point of intersection produced by the lines of cross fire B b and C c to the axis XY, it will be found that the ordinate n G = 18.2 feet, and the ordinate GK = 6.2 feet. So also for the point of intersection of Bb and Ll, we have the ordinate lL = 19.5 feet, and LK = 8.0 feet.

Lines of Fire producing Different Intersections.	Magnitudes of the ordinates representing the distances of the points of cross-fire from the principal axis XY.	Magnitudes of the ordinates estimated on the principal axis XY, from the common origin K, to the points where the preceding ordinates intersect the same.
Intersection of B b with C c	n G = 18.2 feet	GK = 6.2 feet.
Intersection of B b with L l	l L = 19.5	LK = 8.0
Intersection of B b with H h and with E e	q Q = 59.5	QK = 61.[illegible]
Intersection of C c with K k	t K = 47.5	K = 0.9
Intersection of D d with E e	d N = 15.2	NK = [illegible]2.0
Intersection of D d with F f	x R = 32.0	RK = 76.8
Intersection of E e with I i	i O = 19.0	OK = 25.4
Intersection of f F with f F	F = 0.0	FK = 20.0
Intersection of F f with M m	m P = 4.5	PK = 27.8

The danger of fire, from the explosions of the guns taking place, *within board*, has been briefly alluded to; but as the superiority of the curvilineal stern, in this point of view, is strikingly conspicuous, it may not be improper to allude to this part of the subject more particularly.

By comparing Figs. 6. and 7. Plate CCCCXCVII. it will be perceived that, in the old form (Fig. 6.) the muzzle is twenty-one inches *within* the rail, whereas, in the new form, (Fig. 7.) the muzzle is eighteen inches *beyond* the frame of stern: the guns of each being supposed in a fore and aft direction. It is scarcely necessary to insist on the superiority of the latter form above the former, in relation to this very important consideration: since an explosion can never take place *within board*, without obvious disadvantages and danger. When the guns are trained, the evil will be increased in the square stern; whereas, with the greatest possible angle the case will admit in the curvilineal stern, the muzzle is never *within* the stern frame. These disadvantages in the square stern arise from the over-hanging form of that part of the ship, and from the inconvenient distribution of the timbers of the frame.

With respect to the guns of the after broadside ports of the two frigates, it may be observed, that they are under precisely the same circumstances, their muzzles in both cases being *beyond* the side of the ship, and also in the same degree. A fore and aft view is given in Fig. 8. Plate CCCCXCVII.

With the quarter gun of the new form no comparison can be made with the square stern: but by reference to Fig. 7. which represents a view of the quarter part of the Hamadryad, the projection being square from the side of the ship, and the gun run out as far as possible, it will be perceived that it possesses all the advantages of a broadside port, the only difference being a rather less projection of the muzzle, in consequence of the quarter being nearly perpendicular, and not falling in, as is the case at the broadside. Any explosion must therefore pass clear of the side of the vessel, with nearly the same security as if the gun were placed at a broadside port.

Among the many objections that have been urged against the adoption of the curvilineal stern, is the apparently formidable one, that a broadside port has been lost on each side of every ship to which it has been applied. After a careful examination however of this objection with respect to the Hamadryad, Mr. H. feels no hesitation in stating, that so far from this being the case, *it would not be extravagant to assert that a port has actually been gained on each side, by means of the port at the quarter.*

To demonstrate this, (and the great value of this investigation arises from nothing having been adopted hypothetically,) let a reference be made to the line of fire L*l*, Fig. 2. Plate CCCCXCVII. and by which it will appear that the quarter port may be readily and satisfactorily employed as a broadside port: for since it was found possible, by the naval gentlemen who assisted at the experiments, to train the gun at the quarter port into the direction C *c*, forming an angle of 12° *before* the beam, with much greater ease would it be possible to work it in the line of bearing L*l*, *on* the beam. *This circumstance adds therefore to the ordinary and essential uses of the quarter port, the additional advantage of being effectually employed, when occasion requires, in aiding the defence of the broadside.*

Nor should it be forgotten, that the facility with which *all* the guns can be worked in the curvilineal stern for the different points of bearing before described, and the total absence of all the timbers and other obstacles which, in the square stern, occasion so many serious and decided impediments, increase in a very high degree the advantages likely to result from the general application of the new form. To take the example of a man of war becalmed in the bay of Gibraltar, or at the entrance of the Baltic, situations in which our gallant seamen have sometimes been exposed to the irritating and destructive effects of raking fires from gun-boats; is it not apparent from the preceding experiments, that a ship with a curvilineal stern, so circumstanced, would be enabled effectually to resist any attack of this kind? And that even if the vessel so acting on the offensive should vary her position with all the readiness a steam boat is capable of moving, the guns at the quarters and stern ports of a round stern ship could be as readily made to follow her? Nor would it be possible for the attacking vessel to take up any position in the neighbourhood of the stern, without having a gun or guns ready to resist her. This is an advantage which ships constructed on the old principle never possessed, and forms one among the many good qualities of the new.

The introduction of the round stern excited the most violent opposition: and the keenest controversies were excited amongst naval men respecting it. The publication however of some able papers has diminished in a very great degree the hostility so vigorously raised against it. The disapprobation of change, which at one time assumed the loud voice of thunder, has insensibly melted into tones of a gentler kind. Inquiry has been awakened, and many who imagined they saw in the alterations *indications of decay in the martial energies of our marine*, now contemplate it with respect to the superior strength it affords, and the more ample means of defence it unfolds. Some, however, faithful to the ancient form, still regard the circular stern with unabated hostility. But to such it may be said, are we to arrest the march of architectural improvement? Is the new principle of shipbuilding, which has already conferred such transcendent benefits on our country, to be deprived of one of its essential elements? While every other part of our men of war has received accession of strength, is the stern to remain in all its primitive weakness, without receiving a single benefit from the science and enlarged experience of modern times? Can such an anomaly long remain to mock the efforts of human improvement? Is the naval engineer to be doomed perpetually to reflect, that in the magnificent fabric which his genius has raised, science has lent her best efforts to strengthen the mighty system, in all its parts, save *one?* Or is the old system to be persevered in, to afford another exemplification of the maxim that partial strength is general weakness? Is it consistent, moreover, with that noble spirit of advancement, which so preeminently characterises the age, and which in its general operations, confers so great a lustre on our own beloved country, to allow mere feelings of convenience,* and vague and undefined notions of beauty to stand in the way of genuine improvement? Rather let us, by the universal adoption of the circular stern, prove that we only adopt a system which science and sound experience sanction; and that we only advance another step in the career of that improvement which has been so lately introduced into shipbuilding; and that we are no longer enemies to the doubtful forms of beauty, than when they stand opposed to the progress of real improvement.

The period, however, we firmly believe, is not far distant, when the circular stern will be contemplated by all unprejudiced minds, with more real pleasure than that form which has nothing but time and the false perspective of centuries to recommend it; shedding new lustre on the name of its celebrated author, and adding to the other intellectual trophies he has achieved, one not the least valuable; since it will carry with it the unerring symbol of truth: having made its way amidst prejudices of no ordinary cast, and in spite of an opposition of no ordinary kind; time having proved its unquestionable merits, and numbered it amongst its choicest and most valuable treasures.

OF THE STOWAGE OF SHIPS.

On this important subject, we cannot do better than introduce to our readers Mr. Morgan's valuable paper, contained in the first number of his useful periodical work, named, "Papers on Naval Architecture."

* It has been already observed that in the reign of Henry VIII. our ships were without the convenience of a water closet abaft.

By the stowage of a ship is meant the disposition of the ballast and stores. The great effect produced by different modes of stowage, renders this subject one of the most important connected with naval architecture. Most of the properties of a ship depend in some measure on the situation of the centre of gravity, which is determined by the disposition of the *moveable* weights on board. The great difference found to exist in the qualities of the same ship at different times arises principally from alterations in the stowage and trim. The astonishing improvements sometimes said to be made in ships by the removal of small weights might appear questionable; but as the present state of this branch of the science of naval architecture is not sufficiently known to fix with certainty the best sailing trim, the numerous facts related on the authority of men of experience are to be received with the greater credibility, if not admitting the degree, yet establishing the principle.

This subject has received the attention of many eminent scientific men, as well as experienced naval officers, through whose labours very valuable information has been obtained. In France the best memoir on the stowage of ships was several times made the subject of a prize by the Academy of Sciences. Daniel Bernouilli received the prize in 1757. Euler divided the prize of 1759; and Bossut and the younger Euler divided the prize of 1761.

As the situation of many of the weights in a ship are unavoidably fixed by circumstances, the advantages to be derived from an investigation of the stowage of ships can relate only to the *moveable* weights: the ballast, and *part* of the stores.

The quantity of stores and ballast in a ship is the first consideration in the stowage. The number of months for which vessels should stow provisions depends on their class and general service. No ship should, however, be incapable of stowing four months' provisions with the ordinary complement of stores.

The quantity of ballast is dependent on some of the qualities of a ship: chiefly the stability and the lateral resistance opposed to falling to leeward. An increase of ballast must always produce one disadvantage, an increase of the area of direct resistance, which, *cæteris paribus*, would reduce a ship's velocity in the water. By the increase of ballast, however, judicially stowed, the stability of a ship is frequently increased, so that she will carry so much more sail, that the moving power is increased more than the resistance, and consequently the velocity of the ship is increased. The question arising from this consideration is, whether the advantage produced by an increase of ballast could not be obtained by other means without an equal attendant disadvantage? The stability could be increased in a ship to be built by an increase of breadth preserved above and below the water's surface, so far as the immersion and emersion caused by the inclination, and extending considerably forward and aft. The lateral resistance to prevent the ship's falling to leeward, might be increased by the form below, and forward and abaft. By these means it would not be necessary to increase the quantity of ballast so much as is frequently done. This substitution of *form* for *an increase of ballast*, cannot, however probably be carried so far, but that a considerable quantity of ballast will be necessary. To what extent the quantity of ballast in ships may be reduced might probably be ascertained by experiment.

The properties of a ship which are chiefly affected by the stowage are, the stability, rolling, pitching, holding a steady course, ardency or tendency to fly up in the wind, going about, action of the rudder, and the strain of the materials. The manner in which the stowage influences these properties will be best seen by considering them, as far as is possible, independently of other circumstances.

1. *The stability.*—The disposition of the weights of a ship determines the position of its centre of gravity, which, *cæteris paribus*, increases or diminishes the stability according to its being lower or higher in the ship. This is as well known in practice as clearly demonstrable by science. The distribution of the ballast as low as possible, is therefore always necessary when the stability is required to be increased. The nearer the middle of the ship, in the full parts of the body, the ballast is stowed, the lower it will be, and consequently, the greater the stability. This, in almost all cases, is good stowage, in relation to the stability of a ship, as the case is rare when the lading of the ship is of such great specific gravity as to render it necessary to raise the weights, by putting articles of less specific gravity under.

2. *Rolling.*—In estimating the influence of the stowage on the rolling of a ship, it must be considered independently of the stability. The permanent inclination caused by the force of the wind, depends entirely on the stability; but the vibratory action of rolling depends on other causes, some of which are unconnected with the stability. Two ships of equal stability are frequently known to possess very different qualities in this respect; the one may roll slowly and easily, the other quickly and uneasily.

The rolling of a ship is caused by waves striking a ship's side; it is generally deepest either when a sudden change of wind takes place, and the ship sailing free, is struck on the side by the waves, which continue to run in the direction of the wind before the change; or in a calm, when the swell of the sea gives the body of the ship a constant disposition to incline, without any inclining force to keep the ship steady.

The rolling of a ship is sometimes (as has been before remarked,) considered analogous to the vibrations of a pendulum. Supposing some point below the ship to be the point of suspension, the length of the pendulum is measured by each particle into the square of its distance from the centre of suspension, divided by the whole body into the distance of the centre of suspension from the centre of gravity. The length of the pendulum would, therefore, be increased by removing the weight as far as possible from the centre of suspension. The disposition of the moveable weights in a ship, according to this consideration, therefore, to increase the length of the isochronal pendulum, would be to place them as far as possible from the vertical and longitudinal plane passing through the centre of gravity. By the increase of the length of the pendulum, the time of the oscillation is increased, so that the ship's rolling would be proportionally slower.

The analogy, however, between the oscillations of a pendulum and the rolling of a ship cannot be considered strictly correct.

An easier method of considering the effect of the weights on the rolling of a ship, is, simply, by estimating their resistance to rotatory motion by their inertia. As the inertia of any weight is measured by each particle into the square of its distance from the centre of suspension, the placing these weights furthest from the centre of suspension, would most increase their resistance to motion. In a ship, the centre of suspension must be considered to coincide with the centre of gravity, so that the further the weights are removed from the centre of gravity, the greater would be the resistance to quick and uneasy rolling.

The practice of "winging the weight," as it is technically called, suggested by these principles, is found to be fully justified by experience. Care should, however, be taken that the centre of gravity of the weights may not be raised by this disposition, that the stability may not be diminished by it.

Quick and violent rolling is frequently found to be very injurious to the hull and masts of a ship. Many modes of security of the beam ends and ship's sides have been adopted, which have been of great advantage in sustaining the strain caused by this action. Due consideration to form and good stowage are, however always found greatly to reduce the violence of a ship's rolling.

3. *Pitching.*—When a ship is so far passed over a wave, that the fore part is unsupported by the water, the mean vertical direction of the water acting abaft the centre of gravity, causes the bows to pitch forward into the hollow of the wave. This motion, as far as it is influenced by the distribution of the weights, is subject to the same laws as the rolling. The farther the weights are from a vertical transverse plane passing through the centre of gravity, the greater will be their inertia, and consequently, the slower and deeper the pitching. These two motions are, however, to be considered very differently, as to their effect on the ship. The advantage of increasing the time and depth of the rolling has been considered in diminishing the strain of the hull and masts; but the effect of deep pitching must, on the contrary, be considered as disadvantageous, by retarding the velocity of the ship's motion, and rendering it uncomfortable to the men, by the waves breaking over it.

When a ship has passed a wave, the afterpart falls into the hollow of the waves, by the mean vertical direction of the water acting on the foreside of the centre of gravity. This action, which is called scending is affected by the disposition of the weights similarly to the pitching.

The form of the fore and after parts of a ship determines, in a great degree, these actions of pitching and scending; but as other circumstances frequently require a form not the best calculated to regulate them, it becomes the more necessary that the best disposition of the moveable weights should be made for this purpose. It is therefore necessary to bring as many of the moveable weights as possible near the middle of the ship, to reduce the depth of the pitching and scending.

4. *Holding a steady course.*—When a body moves through any fluid, it is necessary that the lateral resistance abaft the centre of gravity should be greater than before it, to prevent the body having a continual tendency to turn round. This disposition in a ship to turn from the direct course, is technically called *yawing*: it increases the difficulty of steering, and retards the sailing. To prevent this bad quality in a ship, the weights should be so placed that the centre of gravity may be before the middle of the ship's length, by which the moment of the lateral resistance abaft the centre of gravity will be increased, and the moment forward diminished.

5. *Ardency.*—The ardency of a ship, or its tendency to fly up into the wind, depends on the mean direction of the water, the ship sailing by a wind, and the position of the centre of effort of the sails. When a ship is fully stored and properly trimmed, the mean direction of the water passes a little before the centre of gravity. By the loss of the consumable stores the trim may, by improper stowage, be so much altered, that a ship, which at first possessed a weatherly quality in a proper degree, may either lose it altogether, or have it altered so much as to destroy the excellency of this important quality. The stowage should, therefore, be so disposed, that the consumable stores should be taken in such proportions from the fore and after parts of a ship, that the good qualities at first possessed may be retained when lightened. This requires great acquaintance with the qualities of the ship to be stowed, as well as great judgment in the disposition of the ballast and stores.

6. *Tacking.*—The resistance a ship experiences, in coming about, depends on the lateral resistance of the parts before and abaft the centre of gravity. This resistance will be proportional to the squares of the lengths of the parts before and abaft the centre of gravity, which will be a minimum when the centre of gravity is in the middle of the length.

7. *Action of the Rudder.*—As the rotation of a ship must always be referred to the axis that passes through the centre of gravity, the momentum of the power of the rudder to turn a ship is proportional to the distance of the centre of the mean resistance of the rudder from the centre of gravity. This consideration would lead to the moveable weights being placed so that the centre of gravity of the ship should be before the middle of the length.

8. *Strain of the materials.*—The inequality between the weights in different parts of a ship, and the vertical pressure of the water at the corresponding parts, causes a continual strain on the ship longitudinally, which produces an arching, sometimes technically called *hogging*. To equalise these two actions, is the mode immediately suggested by the consideration of the cause of arching, as the best method of preventing it. Circumstances, however, prevent the establishment of the equilibrium; great weights will always necessarily be at the extremities of the ship, and the buoyancy of the corresponding parts of the body must always be very inadequate to their support, from the leanness of the fore and after parts of the body. As far, however, as circumstances will admit, the principle should be attended to, of placing the weights where the buoyancy of the body is best able to sustain them. This requires the ballast and heaviest stores to be placed in the full parts of the body, towards the midship section; reserving, however, the immediate vicinity of the mainmast free from the heaviest weights.

These are the principal considerations on the stowage of ships; and it happens fortunately, that the modes of stowage required by a due attention to the qualities influenced by it are generally compatible with one another. *The stability requires the greatest weights as low as possible, which is agreeable to concentrating them towards the middle of the ship's length, which is required to produce the best effect on the pitching, tacking, and strain of the materials. Holding a steady course, and the action of the rudder, require the weights to be placed so that the centre of gravity of the ship may be before the middle, but not so much as to be practically opposed to the consideration of its being very near to the middle, which reduces the resistance to coming about. The rolling requires the weights to be winged, which may be done by judgment and attention, without raising their centre of gravity, which would diminish the stability.*

The result of these observations is, that *the moveable weights in a ship should be so disposed that its centre of gravity may be low and a little before the middle of its length; and that they should be winged as much as possible without raising their centre of gravity.*

Chapman, says, in his Treatise on Shipbuilding, that the centre of gravity of a ship should be between the limits of $\frac{1}{50}$ and $\frac{1}{100}$ of the length before the middle. This proportion he most probably determined by calculations made on different ships in the Swedish service. The centre of gravity of ships of seventy-four guns, stowed according to the English method, as to the height of its situation, is generally from about six to nine inches above the load water line.

These principles govern the stowage of ships, but the manner and degree to which they should be carried into practice, must be ascertained by experiment. A course of experiments on the quantity of ballast, and the best disposition of weights on every class of ships, would be very valuable to the science of Naval Architecture. By determining the proper trim of the different classes of ships, much valuable information would be obtained for the naval architect in making designs. Many calculations, which are made by assuming the set of the ship in water, but which it is afterwards found necessary to alter, would be made with much greater certainty than at present. *It is by a combination of theoretical and experimental knowledge, in this subject as in most others connected with naval architecture, that this science will arrive at perfection.*

ON THE PARABOLIC SYSTEM OF CONSTRUCTING SHIPS INVENTED BY ADMIRAL F. H. CHAPMAN.

The system which is at present used by the Swedish engineers, in the construction of ships, was the result of the labours of the latter years of Chapman's life; it is called the parabolic method, and is explained in a work entitled, *Försök till en Theoretisk Afhandling att gifva åt Linie Skepp deras rätta Storlek och Form Likaledes för Fregatter och mindre Beväpnade Fartyg. af F. H. af Chapman. Carlskrona*, 1806.

The following paper, drawn up by Lieut. A. G. Carlsand of the Swedish navy,[*] is an outline of this description, with some few alterations, which the writer considers may perhaps render the calculations more simple.

By making calculations on a number of ships which have been found to possess good properties, and subjecting the result to scientific investigation, we are enabled to state what displacement and what dimensions a well-constructed ship should have; we can also determine where the centre of gravity, in respect to length, should be placed; but we cannot by the usual methods of construction, without very great labour, determine the area of the midship section, its distance before the middle of the length, and the areas or forms of the other sections, so as to ensure having this requisite displacement, nor that it shall be so distributed that the centre of gravity shall be in the required situation. It was to supply these deficiencies that Chapman invented the method which is the subject of this paper.

As the above-mentioned elements depend upon the areas and situations of the several transverse sections, Chapman endeavoured to discover whether or not these areas, in well-constructed ships, followed any law; and if so, to find the law. For this purpose, he calculated the areas of the sections of several ships; and, in order to make the numbers more convenient, he divided the areas by the breadth of the midship section; then setting off from the water line, at the respective stations on the drawing, distances equal to the quotients, he traced a curve representing the areas, which he called the curve of sections. He then endeavoured to find the equation to the curve, or rather that of another curve which would coincide with this for the greatest length; and he found that if the power and parameter of a parabola were so determined as to allow that curve to pass through three given points of the curve of sections, the two curves would nearly coincide. In the fore body the three points were taken, one forward, one at the midship section, and one midway between. In the after body the points were similarly situated. In some ships the exponent to the curve was higher in the after body than in the fore body, in some it was the same for both: it was also found that there were ships in which the curve of sections almost exactly agreed with the parabola, and these ships invariably bore excellent characters. Chapman consequently concluded, that if the areas of the several sections of a ship were made to follow the law of the abscissas of a parabola, a vessel possessing good sailing qualities might be formed, and the process of construction much simplified.

This account shows that this method is deduced from experience by theoretical investigation; it is applicable to all sorts of constructions, as it only requires that the relative areas of the sections shall decrease from the midship section towards the extremities, in a certain relation which can be varied to infinity; it is therefore equally useful in constructing the sharpest man-of-war, as the fullest merchantman.

It may perhaps be objected, that the alterations which have taken place in the forms of the bottoms of ships, since the introduction of this method by Chapman in 1806, would probably give different results; it is therefore desirable that this should be ascertained by a series of calculations on the bodies of some of the most modern ships which have been found to answer.

Suppose a ship is found to answer well at some given water line AC, Fig. 4, Plate CCCCXCV. Let the areas of the transverse vertical sections be divided by some constant quantity, as, for instance, the

[*] This ingenious gentleman was a pupil of the celebrated Chapman.

breadth, and suppose the distances $a\,b$, $c\,d$, &c. equal to the quotients, to be set off on the respective sections, from the water line; then a curve drawn through the points b, d, &c. will be the curve of sections. It will be found to be convex to the water line at the extremities.

The order of the parabola which coincides for the greatest distance with this line may easily be found.

Let the general equation to the parabola be expressed by $y^n = a\,x$: then it is always possible to determine n and a, so that the parabola shall pass through two points besides the vertex: any two points between b and C may be taken, but it is evident that the farther apart the three points are taken, the longer will the parabola coincide with the line of sections: of course neither point may be in the convex part of the line of sections. It will be found that the point g, at the foremost frame, and h in the middle between g and b, are the points which should be taken.

Draw a tangent to the curve at the point b, which will be of course parallel to the water line; then $m\,h$ and $n\,g$ are abscissas; $b\,m$ and $b\,n$ ordinates to a parabola passing through b, h, and g: put $m\,h = x'$, $n\,g = x''$, $b\,m = y'$, and $b\,n = y''$; then substituting these values in the equation to the parabola, we have

$$y'^n = a\,x', \text{ and } y''^n = a\,x''$$

$$\text{or } n\,.\,\log\,.\,y' = \log\,.\,a + \log\,.\,x' \text{ and}$$

$$n\,\log\,.\,y'' = \log\,.\,a + \log\,.\,x''$$

$$\text{hence } n = \frac{\log.\,x' - \log.\,x''}{\log.\,y' - \log.\,y''}$$

$$a = \frac{y'^n}{x'}$$

$$\text{and } \log.\,a = \frac{\log.\,x'\,.\,\log.\,y'' - \log.\,x''\,.\,\log.\,y'}{\log.\,y' - \log.\,y''}$$

We have now the value of n and a, and by calculating several other abscissas we can trace the parabolic curve. The same operations applied to the after body will give the exponent and parameter of the parabola, which is the most similar to the curve of sections in that body.

It generally happens that the exponents are nearly the same in both bodies, if the place of the midship section be determined in the manner shown in the sequel.

It will be found that the parabola and the line of sections very nearly coincide; the former being sometimes a little within the latter between g and h, and without at the foreside of h; and sometimes, but much more seldom, the contrary. The parabola always cuts the water line at a short distance from the rabbets, this distance being rather greater forward than abaft.

Several American ships of war have been submitted to this method of investigation, which was found to answer very well with their bodies: indeed there can be no great deviation, as the parabola varies according to its exponent and parameter; if the ship is full, a high exponent adapts it to that shape: and if the ship be lean, a small one. If the body has a long straight of breadth, and sharpens quickly at the extremities, by deducting a part in midships from the comparison, the system may still be applied: or if, as is the case generally with English merchant ships, there is a very great draught of water in proportion to the breadth, by deducting a part from the water line downwards, this method may be applied to the remainder.

From this reasoning it appears that ships may be constructed to coincide exactly with the parabolic line, without deviating from the forms which experience has proved to be the most conducive to giving ships good qualities. Chapman stated that this system would most probably be superior to the old one, and the result has confirmed his statement: for ships of the line, frigates, and merchantmen, have been constructed after it, all of which have been very fine vessels.

From the manner in which the curve of sections is formed, it follows that its area, multiplied by the breadth, is equal to the displacement, and that the centre of gravity of the area is in the same transverse section as the centre of gravity of the body: but the area of this curve, supposing it to be a parabola of a certain power, is a known part of the rectangle formed by the greatest ordinate and the abscissa; hence, by making the areas of the sections decrease in the ratio of the abscissas in the parabola, we obtain certain equations between the quantities. To find these equations, suppose the parabolic line, now also representing the line of sections, to be ACB, Fig. 5. Plate CCCCXCV., cutting the water line at some distance from both rabbets; let C be the place of the midship section, and DC the greatest abscissa. Put AB $= l$ and DC $= d$, let the exponent of the parabola before and abaft $= n$, and the displacement $=$ D; then the area of the parabolic line BDACB $= \frac{n}{n+1}\,.\,l\,.\,d$, and the displacement $= \frac{n}{n+1}\,l\,.\,d\,.$ B (B representing the breadth;) but d B $=$ area of the midship section; hence

$$\frac{n}{n+1}\,.\,l\,.\,(\textit{area of midship section}) = \text{D} \;.\;.\;.\; (1).$$

Let E be the middle point of the water line AB, which we may call the construction water line, F the place of the centre of gravity in point of length; let ED, the distance the midship section is before the middle of the water line, $= k$, and EF, the distance the centre of gravity is before the middle, $= a$: we will now determine the place of the midship section in reference to the situation of the centre of gravity F.

As BCD represents the displacement of the fore body, and CDA that of the after body, the moments of these two parts will give the common moment.

The centre of gravity of the parabolic area is at a distance from the abscissa DC

$$= \frac{n+1}{2\,n+4} \times \text{the ordinate DB;}$$

and for the parabolic area DCA it is

$$= \frac{n+1}{2\,n+4}\,\text{DA}.$$

The moment of DCB from the point E

$$= \left(k + \frac{n+1}{2\,n+4}\,.\,\text{DB}\right)\,.\,\text{DCB},$$

and the moment of DCA from the same point

$$= \left(\frac{n+1}{2\,n+4}\,\text{DA} - k\right)\,\text{DCA}:$$

But the areas of DCB and DCA are proportional to DB and DA, and the sum of the above moments $=$ EF . BCA, or $a\,.\,k\,.\,l$ representing the area; hence

$$a\,l = \left(k + \frac{n+1}{2n+4}\,\text{DB}\right)\,\text{DB} - \left(\frac{n+1}{2\,n+4}\,.\,\text{DA} - k\right)\,\text{DA}.$$

$$= -\frac{n+1}{2n+4}(DA^2 - DB^2) + k(DB + DA)$$

$$= (DA + DB) \,.\, \left(-\frac{n+1}{2n+4} \,.\, (DA - DB) + k\right)$$

but DA — DB = $2k$, and DA + DB = l: hence

$$a\,l = l\,k \,.\, \left(1 - \frac{n+1}{n+2}\right)$$

$$a = k \,.\, \frac{1}{n+2}$$

or $k = a \,.\, (n+2)$ . . . (2).

That is, if the midship section DC is placed at such a distance k from the middle point of the construction water line, the centre of gravity will be in the point F assigned to it.

These two equations, (1) and (2), form the principal foundation of the parabolic method of construction. In the first equation, any quantity may be known by assigning values to the others; and in the second, by fixing a value for the distance of the centre of gravity before the middle, the place of the midship section will be known; then, having by the first equation found the exponent of the parabola, any abscissa, GH or KL, may be calculated. Suppose, for instance, GH to be required; then, in the first assigned equation $y^n = a\,x$, r is known; also y and x are known for a certain point B, through which the parabola passes; the value of y for this point is DB. and of x is DC. This gives

$$a = \frac{DB^n}{DC} = (\text{by putting } DB = f)\,\frac{f^n}{d} \quad . \; . \; . \; (3).$$

Now GH is easily determined in the above equation, by assigning a value to CG, if CG or any other ordinate is expressed by y', the corresponding abscissa GH = x' is determined by the equation

$$x' = \frac{y'^n}{a} \;.\;.\;.\; (4).$$

This equation is sufficient for calculating the areas of all the sections for the fore body; and for those of the after body we have the equation (3), in which, by substituting f for DA, we get the value of the parameter, a', of the parabola of the after body, and substituting this value for a in equation (4), and giving to y' any value CK, a corresponding abscissa LK is obtained; and in the same manner as many may be found as may be thought proper. It is evident that GH and LK must be subtracted from the largest ordinate DC, to give G′H and K′L, which represent the areas of the corresponding sections.

This method of first calculating the abscissas and then subtracting them, may appear indirect, as the true lines G′H and K′L could have been obtained at once by transforming the equation of the parabolic line to another, beginning at the point D; but it would then have lost its simplicity, and the calculations would not have been easier than by this method. One thing may however be done, which is, to substitute the area of the midship section, instead of its quotient, by the breadth; by which the whole areas of the other sections will be obtained, instead of the lines which represent them.

The principles of the parabolic method being now explained, it will be easily seen how very useful its application is to the comparison of all ships, whether they were constructed with or without reference to it.

By referring to equation (1), we find that the displacement, area of midship section, and the construction water line, being known, the exponent of a parabola that coincides most nearly with the line of sections is easily found, and we shall have (putting M for the midship section) the value of

$$n = \frac{D}{l\,M - D} \quad . \; . \; . \; . \; . \; . \; . \; (a).$$

This value of n shows the degree of fulness of the ship: and as it refers us to a geometrical line, it gives us at the same time a geometrical and arithmetical expression for the relative fulness, and is in consequence preferable to the method which is sometimes used,—that of giving the proportion between the displacement and the circumscribing solid, which only gives an arithmetical expression.

This parabolic method may also be applied to show the relative fulness of the midship section of any of the water lines, of the displacement with respect to the water line, and of several other elements.

Let ABC Fig. 6, Plate CCCCXCV. represent a midship section, and let EF be a tangent to the curve at the point of contrary flexure C; the small area ECD, not being of any importance, may be neglected. If the midship section is at all similar to those usually given to ships, a parabola may be assigned which shall pass through the points B and C, and have nearly the same area with the midship section, and also nearly coincide with the curve; so that the exponent will afford means of ascertaining its relative fulness.

Call the breadth at the water line AB = $\frac{1}{2}$B, the depth AE = h, and the area ABE = $\frac{1}{2}$M, and let m be the exponent of a parabola having the same area; then

$$\frac{m}{m+1} \,.\, \tfrac{1}{2}\,B \,.\, h = \tfrac{1}{2}\,M$$

$$\text{and } m = \frac{\frac{1}{2}\,M}{\frac{1}{2}\,B\,h - \frac{1}{2}\,M} = \frac{M}{B\,h - M} \quad . \; . \; . \; (5).$$

In the same manner the exponent may be found for the water line, by supposing a parabola with its vertex at the greatest breadth, and passing through the points in which the water line cuts the middle line. Suppose the exponent of this parabola = r, the length on the water line = L, and, as before, the breadth = B; also let the area of the water line = W; then

$$\frac{r}{r+1}\,L,\ \tfrac{1}{2}\,B. = \tfrac{1}{2}\,W$$

$$\text{and } r = = \frac{W}{BL - W} \quad . \; . \; . \; . \; (6)$$

Lastly, suppose the areas of the several water lines from the load water line downwards to decrease in the proportion of the abscissas to a parabola, and let the exponent = s, the depth from the water line to the tangent of the midship section = h, the displacement = D, and the area of the water line = W; then

$$\frac{s}{s+1}\,W\,h = D$$

$$\text{and } s = \frac{D}{hW - D} \quad . \; . \; . \; . \; . (7.)$$

By calculating these different exponents for ships already built, and which have been found to possess good qualities, a very correct idea of their shape will be obtained, which, in making new constructions, may be referred to; and after a very short practice, the constructer will be enabled to determine, not only the principal dimensions, but the outlines of the body before a drawing is begun.

A collection of such calculations was begun by Chapman, and has, since his time, been considerably augmented; we now, therefore, know what the value of the exponents ought to be, in the different classes of ships, for the services to which they are destined. It is always found that large ships are fuller than small ones, and, in consequence, have larger exponents; and that merchant-men, have larger exponents than men-of-war of equal size.

The exponent of the line of sections in the Swedish navy, in ships of the line, varies from 2.5 to 2.7: of the midship section, from 5 to 3.8; of the water line, from 6.6 to 5.9: and of the displacement, from 2.2 to 1.8: of course the larger exponent belongs to the larger class of ships.

In frigates, sloops, and brigs, they are smaller: the exponent of the line of sections varies from 2.3 to 2.1; of the mid-ship section, from 3 to 1.9; of the water line, from 5.2 to 3.25; and of the displacement, from 1.6 to 1.25. These exponents show that small ships have much larger dimensions in proportion to their displacements than large ones.

The above results were obtained from the displacements and breadths, not including the plank: and the length is that of the construction water line, which, in Swedish ships, is $\frac{1}{24}$ less than the whole water line between the rabbets, $\frac{7}{10}$ of which deduction is made from forward, and $\frac{3}{10}$ from aft. In finding the exponent for the water line, its whole length between the rabbets is taken.

Of course these calculations are equally applicable with the plank on as with it off: in the first-mentioned case the sections near the extremities will have, relatively to the midship section, a larger area, and there will therefore be scarcely any hollow at the ends of the curves, and it will not be improper to take the length of the water line, the whole length between the rabbets.

The following tables are given as an illustration of this method:—

	Length on the water line.	Breadth ex-treme.	Depth from the water line to the lower edge of the Rab-bet.	Dis-place-ment, in-cluding the plank.	Area of the load water section.	Area of the mid-ship sec-tion.
	ft.	ft.	ft.	cub ft.	sq. ft.	sq ft.
Nelson -	[illegible]	[illegible]	25.5	[illegible]	[illegible]	1029
Bulwark -	[illegible]	49.0	19.8	[illegible]	7706	791
Endymion	157.0	41.9	16.0	55807	5656	510

Then from the equations (a), (5), (6), and (7), the following may be obtained:—

	Value of *n*, the exponent of the line of sections.	Value of *m*, the exponent of the midship section.	Value of *r*, the exponent of the water line.	Value of *s*, the exponent of the displacement.
Nelson -	2.836	6.9447	11.8034	2.3445
Bulwark -	2.851	4.4141	6.8273	2.2538
Endymion	2.300	3.1795	6.1235	1.6088

From this table of exponents, we may judge with certainty of the shape of the vessels. The *Nelson*, for instance, has a very full midship section, and an exceedingly full water line, but she is not relatively so full towards the extremities as the *Bulwark*, and her displacement is not relatively much fuller than that of the *Bulwark*. The *Bulwark* has a small midship section, is full towards the extremities, and has a very large water section in proportion to her displacement. The *Endymion* is a very sharp ship of her class, has a small midship section, is rather clean towards the extremities, but her water line is not very sharp: its proportion to her displacement is extremely large.

The four exponents which have been described, will separately only show the degrees of fulness in one direction; but they may be combined in such a manner as to express, at the same time, the longitudinal and transversal fulness; to effect which, the value of the area of the midship section $= \frac{m}{m+1} \cdot \mathrm{B}\,h$ must be substituted in equation (1), which gives

$$\frac{n}{n+1} \cdot \frac{m}{m+1} \cdot l \,.\, \mathrm{B} \,.\, h = \mathrm{D} \quad . \quad . \quad . \quad (b);$$

also by substituting the value of $\mathrm{W} = \frac{r}{r+1}\mathrm{B} \,.\, \mathrm{L}$ in the equation (7), we have

$$\frac{r}{r+1} \cdot \frac{s}{s+1} \,.\, \mathrm{L} \,.\, \mathrm{B} \,.\, h = \mathrm{D} \quad . \quad . \quad . \quad (c).$$

In these equations the products $\frac{n}{n+1} \cdot \frac{m}{m+1} \cdot \frac{r}{r+1} \cdot \frac{s}{s+1}$ show the relative fulness of different ships, in comparison to the circumscribing parallelopiped. When the construction water line is equal to the whole water line, as was supposed in calculating the foregoing table

$$\frac{n}{n+1} \cdot \frac{m}{m+1} = \frac{r}{r+1} \cdot \frac{s}{s+1} \,.$$

By this equation any error in determining the exponents may be detected; and also by using the whole equations (b) and (c), errors in the dimensions or exponents will be detected.

By a method of interpolation, formulæ of very easy application have been deduced; by which the depth of the centre of gravity of the displacement below the water-section, the height of the metacentre, and several other essential elements, may be approximated to, without the usually long calculations: and thus most of the qualities of a ship, which are determinable by calculation, may be ascertained, compared, and altered, with very little trouble, before the construction is begun.

In order to apply this method of construction to practice, nothing more is requisite than to know the limits between which the exponents generally are for the class of ships in question, the proportion between the principal dimensions, and the distance the centre of gravity should be before the middle of the load water line. In Sweedish ships of the line, and frigates, the distance of the centre of gravity of the displacement before the middle of the load water line, is between $\frac{1}{70}$ and $\frac{1}{60}$ of the length, and in smaller vessels it is a little more, depending on the manner in which their stores and rigging are distributed. This quantity being determined, the weight the ship is to carry, the weight of the hull, and the relative proportions of the different dimensions, or the value of the exponents; the calculations will give the areas of every section, leaving the constructer the power of giving them whatever form he may wish.

By inserting the calculations of a steam-boat* which I have very recently constructed according to this method, its application may perhaps be more clearly illustrated.

Suppose the ratio of the breadth to the length to be α, and that of the breadth to the depth to be β, by substituting them in the equation (b), it will become

$$\frac{n}{n+1} \cdot \frac{m}{m+1} \cdot \alpha \cdot \beta \cdot B^3 = D.$$

The values of m and n are known, being assumed from former experience; the displacement is determined by the weight of the engines, added to the weight of the stores, &c. and an approximation to the weight of the hull. By assigning values to α and β, the value of B is obtained, and from that the values of the length and depth. The dimensions being now known, the scantling may be determined, and the true weight of the hull estimated; which, if very different from the approximation which was used, will cause a corresponding alteration in the dimensions, &c. With a steam boat, the stability is of minor importance; therefore it is not necessary to refer to equation (c).

The vessel in question is intended for two 25 horse power engines, the weight of which, with the necessary stores and the other articles, was estimated to be about 2050 cubic feet of water, and the approximation which was at first made to the hull was 1850 cubic feet, which supposed the whole displacement to be 3900 cubic feet.

The vessel was intended to be sharp both at the midship section and at the extremities; hence n was taken = 2.12, and m = 3.0; the proportion between the length and the breadth, or α, was taken = 5.25, and that between the breadth and the depth, or β, = 0.32; by substituting this value in the equation, we have

$$B = \sqrt[3]{\frac{3900 \cdot 3.12 \cdot 4}{2.12 \cdot 3 \cdot 5.25 \cdot 0.32}} = 16.58$$

$$\text{Length} = 5.25\ B = 87.04$$
$$\text{Depth} = 0.32\ B = 5.31.$$

By calculating the weight of the hull according to these dimensions, it was found that the approximation was too small by 175 cubic feet; by adding this quantity to the displacement, and retaining the other values, it will be found from the above equation that the

$$\text{Breadth} = 16.822$$
$$\text{Length} = 5.25 \cdot 16.822 = 88.315$$
$$\text{Depth} = 0.32 \cdot 16.822 = 5.383$$

The weight of the engine, its situation, and its centre of gravity, must determine the place of the centre of gravity of the vessel, which was found to be about 2.25 feet before the middle of the length, on the construction water line: and consequently from equation (2), the situation of the midship section was determined to be 9.27 feet before the middle of the construction water line.

The stations of the other sections were determined by the room and space. The parameters for the fore and after bodies were first determined by substitution in the equation (3.) In the fore body

$$f = \frac{l}{2} - k = \frac{88.315}{2} - 9.27 = 34.887$$

and in the after body

$$f = \frac{l}{2} + k = 53.427$$

The area of the midship section from equation (5),

$$= \frac{m}{m+1} B\, h = \tfrac{3}{4} \cdot 16.822 \cdot 5.383$$
$$= 67.912 \text{ square feet,}$$

and the half area = 33.956.

Hence by equation (3), the parameter of the fore body

$$= \frac{(34.887)^{2.12}}{33.956} = 54.895$$

and for the after body

$$a' = \frac{(53.127)^{2.12}}{33.956} = 135.499$$

The calculations for the sections are contained in the following tables:—

For the Fore Body, $x = \frac{y^{2.12}}{54.895}$				For the After Body, $x = \frac{y^{2.12}}{135.499}$			
Sections. Name.	Sections. Distance from the Midship Sec. or y	Abscissa or x.	Half the Midship Sec. — x	Sections. Name.	Sections. Distance from the Midship Sec. or y	Abscissa or x.	Half the Midship Sec. — x.
	Feet.	Sq. Ft	Sq. Ft		Feet.	Sq. Ft.	Sq. Ft.

Midship Sec.	0.00	.0	33.96	12	18 00	3.382	30 578
				8	12 00	1.432	32 528
				4	6 00	.329	33.631
				Midship Sec.	0.00	0 0	33.96

The areas of the sections being thus determined, the construction of the draught was begun. The midship section and one or two sections in each body being drawn in, and their areas ascertained to agree with the tables, one or two diagonals were got in, and the rest of the sections drawn, always keeping their areas precisely equal to those given by the table. The direction of the diagonals at the extremities, determined the places of the stem and stern post rabbets, and from that the length of the whole load water line was found to be 0.44 feet longer than that of the construction water line; viz. 0.33 at the fore end, and 0.11 at the after end; consequently the length of the load water line between the rabbets = 88.755 feet.

As in a ship constructed according to this method, the situation of the centre of gravity, with respect to

* The subject of steam boats will be resumed in the concluding part of the article.

the length, and also the displacement, are known correctly; during the progress of the work much tedious arithmetical calculation is avoided; and after very little practice it will be found that the forms of the different sections may, with great ease, be drawn to contain the requisite areas; and I am confident that by the general adoption of the method, an amazing saving of time and trouble would be effected.

ON PRACTICAL CONSTRUCTION.*

When a draught of a ship is formed upon the principles which have been laid down, adapting them as much as possible to the nature of the service on which she is designed to be employed, and to the seas or rivers which it is intended that she shall navigate, it becomes the duty of the practical builder to carry into effect the views of the constructer; and the first operation which he has to perform, is to delineate correctly, or as it is usually called, lay off the plane upon the mould loft floor. This practice has usually been considered as coming within the province of the practical builder, and may certainly be correctly performed, without the aid of mathematical learning: but in this, as well as in many other of the useful arts, a knowledge of geometry will correct old methods, or strike out new to forward the architect in his views and operations.

The naval engineer, after having formed his plan of the ship according to certain prescribed dimensions, furnishes the practical architect with the sheer draught, Fig. 1. Plate CCCCXCVIII. a plan of the form of the body at various sections, (Fig. 2.) a half breadth plan, (Fig. 3.) and a scheme of the principal dimensions of the ship, and the scantlings of the timbers, planking, &c. The *sheer draught* or plane of elevation, is chiefly useful for the purpose of giving the length of the ship, the depth in the hold, the hanging of the decks and their height from each other, the longitudinal sheer and height of the topsides at the various sections, the rake of the stem and stern post, with the overhanging of the stern. Upon this plan also is delineated the cutting down line of the floors, the draught of water at which it is intended the ship shall sail; the situation of the wales, the spacing of the timbers, the number, position and dimensions of the parts; the situation of the masts and channels, and the form of the gripe and headrails. The *body plan* or vertical plane of the timbers, gives the form of the ship transversely at different sections, corresponding with those similarly marked on the sheer draught, and with which they agree in height; and the half breadth plan or horizontal plane, shows the form and breadth of the frame of the ship at parts cut by horizontal lines, usually denominated waterlines, or by diagonal ones, which either show the length of the several timbers which form the frames or the stations of the ribbands or harpens, which serve to keep the frames in their places before the planking is brought on; these lines, but more particularly the diagonal lines, are used to prove that the sections on the body plan are fair. The obliquity of the cant timbers in the fore and after bodies is also shown on this plan.

To prevent the inaccuracy likely to take place in transferring the several dimensions of a ship from a drawing on a small scale to the actual size intended, the builder is furnished with a scheme of scantlings, which gives in words at length, or by figures, the principal dimensions, the breadth and thickness of the several timbers, (technically called their siding and moulding,) the nature and sizes of the fastenings, the rounding and dimensions of the beams, the thickness of the external and internal planking, decks, clamps, and shelf-pieces.

Being furnished with these plans and information, it becomes the duty of the practical builder to lay down the ship. The drawing furnished by the engineer being usually made on a scale of one-fourth of an inch to a foot, it is necessary to place the projection on the floor forty-eight times their size, in order to make mouldings for providing the timbers of the frame. This laying off the ship is performed chiefly by horizontal and diagonal lines cutting the body in various directions: the greater number of these employed, the more likely to be the fairness of the lines of the body, and the accuracy of the work.

Vertical lines are also used to lay down the after body: the variety of positions of the timbers, particularly in ships with square sterns, is such as to require in this part of the body the greatest nicety. When the builder is satisfied with the accuracy of the lines, they are slightly raised on the floor to prevent obliteration. It has sometimes been considered that great nicety is not required with the square frames; but care should be taken to conform as nearly as possible to the form and dimensions given, or difficulty will be experienced in adapting the cant frames to the body. In fine, except a ship be accurately laid down, the labour of the engineer has been employed in vain, as the best-constructed plan may be rendered nugatory for a want of due attention in the performance of this duty, and will also give eventually considerable trouble to the practical constructer in adapting the frames to their positions. To give the methods in use for laying down the several parts of a ship would far exceed our limits: and those of our readers who may wish to be informed on all these points are referred to Stalkart's *Naval Architecture:* to *The Elements and Practice of Naval Architecture,* third edition, or to Fincham's *Directions for Laying off Ships on the Mould Loft Floor.*

Before we enter upon the mode of combining, and the means used to unite the several pieces of timber and metals which constitute a ship, so as to form a whole, we must necessarily digress to give some account of the new mode of construction introduced into his Majesty's navy in the year 1810, by Sir Robert Seppings, who is now surveyor of the royal navy, with the modification which time and experience have enabled him to introduce to bring the plan to its present state of perfection.

The chief circumstances to be guarded against in shipbuilding are, a transverse alteration of form by a separation of one side of the ship from the other, but principally a longitudinal one by the two ends being depressed and the middle rising, which is termed arching or hogging, or in some cases the middle sinking, which is called sagging. The transverse alteration results generally from an imperfect attachment

* We are indebted for the article on Practical Construction to J. Knowles, Esq. F. R. S. secretary to the Committe of Surveyors of the Navy.

of the ends of the beams to the side of the ship, and the want of connexion between beam and beam and the longitudinal one, by the weights placed in the body in no degree corresponding with the displacement of water at the several sections. It is the object of Sir Robert Seppings to prevent these changes in figure by constructing ships according to a new application of matter, by which the strains to which they are subject shall be more equally divided throughout the fabric, and the material placed in such directions as are best adapted to resist those forces; and also by a new combination of the parts of their frames, so as to be enabled to bring into use timber which, from form, its smaller size and less length, shall be more easy to be obtained, and therefore less expensive. These improvements have been completely successful, and on this subject, we cannot do better than quote the opinion of a select committee of the House of Commons, which is given in their third report on Finance.

"Your committee deem it their duty particularly to notice Mr. Seppings, one of the surveyors of the navy, to whose abilities and exertions the country is mainly indebted for many of its most valuable improvements in naval architecture; the ingenious models of which have been submitted to the inspection of your committee, with all the necessary explanations of their several uses and application. Your committee do not pretend to describe or appreciate with accuracy the value of these improvements, to estimate which to their full extent, requires considerable professional experience: they are, however, fully convinced, that the result of them will be to effectuate, in the construction of ships of war, a great saving of expenditure to the public, and to secure a proportionate economy of human life, arising from their superior durability, and the great power of resistance to the elements, and to the casualties incidental to nautical life, which the modern system of keeping our ships at sea, at all seasons, and in all weathers, has rendered of the utmost importance. These services, although they have nothing of that brilliancy which forcibly attracts public admiration, will continue to confer a lasting benefit to the British nation long after that period when the beneficial effects of victories, however splendid, shall have passed away."*

* For these splendid and important improvements, Sir Robert Seppings was rewarded with the Copley medal by the Royal Society, the highest and most glorious distinction that that truly eminent scientific body can confer; and as the improvements which this honourable distinction were designed to commemorate, may be regarded as constituting an era in naval architecture, we add the speech made by the president (Sir Joseph Banks) on presenting the medal to Sir Robert, then Mr. Seppings.

"In offering to you this testimonial of the regard of the Royal Society, it gives me particular pleasure to remark, that the improvements which the council of the Royal Society have thought worthy of such a distinction, consist in the application of the first principles of mechanical science to objects of the highest importance, both for the preservation of human life and for the extension of national glory. The first and greatest of the ancient geometers is well known to have exercised his sublime talents in the investigation of the properties of floating bodies of various forms, and many of the most celebrated of modern mathematicians have made the science of naval architecture a favourite subject of research; but in no instance have these elaborate speculations led to a more important practical result than your ingenuity, judgment, and experience have enabled you to obtain, from a combination of arrangements depending chiefly on a very simple and well-known principle, and subservient to the strength and stiffness of the structure of ships, and to their power of resisting the impression of external force, and the various causes of decay.

"In the first of the papers which you have presented to this society on the subject, you have laid down the general doctrines on which your improvements have proceeded; your great object has been to establish oblique braces and riders, situated nearly in the directions of the diagonals of the squares made by the common frames and planks of a ship; and by means of the more effectual resistance which they afford, to obviate all such changes as tend to alter the angles of those squares, and especially that which is denominated arching or hogging, a change which depends immediately on the greater pressure of the water on the middle of the ship where the displacement is the greatest, while the weight is necessarily extended more towards the extremities: and you have succeeded in reducing the extent of this alteration in a newly launched ship of 74 guns, from 4 or 5 inches, which had been its usual magnitude in the hands of the best workmen, to 1 or 2. You have observed that no common carpenter makes a gate of vertical and horizontal bars only without a brace in an oblique direction: and you have found by experience that a solid wall of planks, although the braces are not so essential to it as to a frame, is still materially strengthened by the addition of diagonal riders; and by such riders below the gun deck, and by braces and trusses of smaller dimensions above it, you have so strengthened the whole fabric of the ship, as to increase the resistance equally in every part, very truly observing that any partial weakness does away the whole benefit of general strength.

"But you have not confined your attention to the arrangement of these oblique pieces only, in preventing the effect of arching: you have opposed an obstacle to the change perhaps still more insurmountable, in the additional resistance which you have enabled the lower part of the ship to oppose to compression, by filling up the spaces between the timbers, from the neighbourhood of the keel to the orlop, with firm blocks of old seasoned wood tightly wedged into all the vacancies, which were formerly only receptacles of dirt and vermin, affording ample opportunity for the accumulation of moisture and foul air, equally noxious to the durability of the ship and to the health of the seamen; and you have found that the additional firmness given to the bottom of the ship by this construction fully superseded the necessity of the inner planking or ceiling, and afforded at the same time greater strength and more space in the hold; allowing the ballast to be stowed lower, and increasing at once the buoyancy of the ship and her stability.

"For attaching the beams of a ship to the sides, you have introduced, under each of the decks, a shelfpiece running in a longitudinal direction, which also affords you considerable firmness in resisting a lateral force, and which you employ in concert with a compact iron knee attached at the one end to a chock supporting the shelfpiece, and at the other to the beam, which is thus tied with great firmness to the side. The planks of your decks are also arranged according to your general principle of obliquity, repaying you for some little sacrifice of longitudinal strength, by the great resistance they oppose to transverse forces, as well as by their co-operation in giving strength to the connexion between the decks and the sides, being strongly united to the sides by means of the pieces called waterways, which run along the angular junction, and which are coaked both to the planks and to the sides.

"It cannot be a just cause for lessening the satisfaction which you are entitled to derive from the success of your improvements, that others should have formerly attempted to introduce arrangements of a nature somewhat similar to your oblique braces or riders, but should have done it so awkwardly and unskilfully as to have failed altogether in obtaining any practical benefit from their imperfect inventions. If indeed the merit of mechanical improvement belonged exclusively to those who first had a vague notion of their possibility, the world would be filled with idle schemers and dreamers, multiplying their crude conceits for the mere chance of hitting upon accidental combination, which, when the hands of more industrious and skilful men had

As the arching of ships has been considered in all times as their most serious defect, it has been the object of maritime nations to take measures to prevent it; and we find that some of the ablest mathematicians and engineers have turned their attention to this object, and that their views have been for the most part the same, that of placing some of the materials in a diagonal direction, that the forces may act in the direction of their fibres, either by pulling or pressing upon them, the strongest direction in which materials of metal or wood can be placed. The mode of application in each case has differed according to the notions of the projector. These plans, however, have been severally abandoned after sufficient trial, and the causes assigned were the want of abutments; they are detailed with much ingeniousness by the Baron Dupin in his paper before quoted.

It remained for the genius of Seppings to adapt successfully the laying of the materials diagonally in shipbuilding to a considerable extent, and by a new and happy combination, by substituting the triangle for the rectangle, to effect the purpose so long desired. On which plans (Plate CCCCXCVIII. Fig. 1.) all ships and vessels belonging to our navy are now constructed; nor has it been confined to this country, for the advantages being so apparent, those ships of war which have been recently built by most foreign powers have also been constructed thereby. The arching of ships at the present time is comparatively nothing, and there are many instances of vessels built according to this method, having been saved, which would inevitably have been lost had they been constructed according to the method formerly practised.

As the strength of ships to resist the impulse of waves and accidents from shot, or from taking the ground, not only depends upon the manner in which they are put together, but also upon the size of the material employed, we shall give a scheme of scantlings for all classes according to the latest improvements.

Principal Dimensions and Scantlings of a Ship of each class, built according to the present improved method of construction.

brought it to perfection, they would be too happy to claim as their own legitimate offspring Other countries may be extremely fertile in speculations of this kind, but Great Britain has long been distinguished for practical excellence in arts and in sciences; and we may willingly consent to share with others some portion of the glory of original invention, provided that we retain as our peculiar patrimony the highest perfection of actual execution.

"We must, however, endeavour to keep always in view the advantage to be obtained by a combination of scientific reasoning with practical experiment; and while we admit the benefit to be derived from strengthening a ship with braces such as yours, we may with great propriety make use of some theoretical principles for determining the situation of the weakest parts which limit the strength of the whole fabric.

"Another Fellow* of this society, distinguished for the accuracy of his physical and mathematical determinations, has given an example of the mode of calculating the strain on the different parts of a ship, derived from the weight and from the pressure of the surrounding medium, and his calculations have been confirmed by a foreign contributor† to our transactions, who has very ingeniously obtained a simple and easy mode of finding the point of a ship at which the longitudinal strain is the greatest, by proving that this point must divide the length in such a manner that the weight of the portion of displaced fluid on either side of the point may be precisely equal to that of the corresponding portion of the ship and her various contents, while, in all other parts, there is an excess or defect of the weight on each side, compared with the pressure.

"You have informed us in a later communication, that not fewer than 38 sail of the line and 30 frigates have been constructed or refitted upon the principles of your method. You have recorded an experiment on the temporary stiffening of an old and worn out ship by oblique pieces, in which the arching was increased 3 inches, as soon as the frames were removed from the hold, and 3⅜ more upon the removal of the braces which had been placed diagonally in the ports, thus demonstrating the nature of the change on which the arching depends, and the proper direction of the forces to be employed for resisting it. You have stated the arching of the best 120 gun ships of the old construction as amounting to 9 inches, while the Howe, built upon your own plan, arched less than four. And you have adduced evidence to prove that in the severe engagement at Algiers, the quarter deck of the Active, laid in the usual manner, was much more injured by the firing than the other decks which had their planks arranged diagonally; and that the result of a comparative experiment in the Northumberland was equally favourable to the merits of your diagonal decks.

"I have now, therefore, only to congratulate you on a success as ample as your most sanguine wishes could have anticipated; and on a professional advancement and encouragement as liberal as becomes an equitable and enlightened administration to have bestowed; and to hope that your labours may still long continue to be immediately employed in the service of your country, and ultimately, if such a necessity should again arise, in the vindication and preservation of the liberties of mankind."

* Dr. Thomas Young, Foreign Secretary of the Royal Society.

† The Baron Dupin.

* It is usual to work the upper edge of the thick stuff under the main wales of the same thickness as those wales, gradually diminishing the thickness of the planks until the lower edge of the lower stroke is wrought to the same thickness as the plank of the bottom.

The first operation necessary in building a ship is, to place pieces of wood on the slip destined to receive her, about four feet apart, for the reception of the keel: these are called blocks, and are laid at a declivity of ⅝ of an inch to every foot of the length to which they extend, or at an angle of 3° 20′. The keel is usually composed of elm logs, scarphed and bolted together. When it is secured on the blocks by treenails, the dead-wood forward and abaft is placed thereon, the form thereof is given by the line shown in the sheer draught called the cutting down line: as *a* (Plate CCCCXCIX. Fig. 10); the floors are then crossed in the keel, or the half floors put in place, (Plate CCCCXCVIII. Fig. 6,) the stem and stern post are raised, and if the vessel is to be built with a square stern, a frame is got up called the stern frame; this is composed of the stern and inner posts, with horizontal timbers fastened in their middle to the stern post, called transoms, and timbers which give the form to the sides of the stern called fashion pieces. In ships with circular sterns, the timbers are carried round with the same uniformity as in the sides, in order to give strength and security; (Plate CCCCXCVIII. Fig. 4;) those in the fore and after bodies of all ships, are canted so as to give the requisite forms. The frame timbers are formed into bends, being composed of 1st, 2d, 3d, 4th, and 5th futtocks, and top-timbers, (the number of futtocks varying according to the sizes of the ships and lengths of the timbers,) the first futtock a butt on the cross pieces, the second on the head of the floor or half floor, as the case may be, the third on the first, and so on throughout the assemblage, care being taken that the timbers be so disposed that the strength of the whole body be lessened as little as possible by the necessity of having them cut off by port holes.

The heads and keels of the timbers of the frame are converted square, so as to form abutments, and are united with coaks, which are let in two inches into the head of the one timber, and two inches into the heel of the other; when these timbers are properly trimmed, they are bolted together so as to form two bends of timbers in each connected frame. When all the bends are raised and secured in their proper places (so as to give the form of the body,) by shores, ribbands, and cross spauls, the keelson is put in place and bolted, and the ship is then said to be completed in frame, or to apply a term used of an animate to an inanimate body, the skeleton is formed. In this state the frames of ships of the line remain at least twelve months, in order that the vegetable juices may be evaporated before the planking is commenced: those of frigates and smaller vessels six months: this is technically called seasoning.

The frame of a ship is usually converted in its siding from ¼ to ½ an inch larger than the required dimensions, and the heads of those timbers which remain naked, are generally six or eight inches longer than the given scantlings. These are termed overcast. Before the planking is commenced, the frame is dubbed over with an adze till wrought to its proper dimensions, and the timbers are reduced to the length required.

The main wales and thick stuff over them are then brought on coaked to the timbers, and fastened also by bolts and treenails, these are worked top and butt, or anchor stock fashion, or with parallel strokes, according to the nature of the materials employed and their economical use; the ship is shored by the main wales, which shores remain until her completion, to prevent any alteration in form.

The orlop clamps and shelfpieces are then worked, and the beams and half beams placed thereon, these are coaked and bolted thereto, the former are also united to the keels of the chocks under the gun-deck beams by the plates. A solid bottom being a principal feature in the new mode of shipbuilding, not only to give strength to the fabric, but also security to the seamen in case of accident to the plank of the bottom by striking upon a rock, this operation is carried into effect by filling the smaller interstices between the lower timbers as high as the floor heads with strips of wood, and thence upwards by driving firmly in the openings between the frame timbers, on the outside, pieces of oak three inches thick, until they make a fair surface with the timbers; on this is placed a composition formed of two parts of lime of a particular description, called Parker's cement, and one part of drift sand, the mixture is placed on the outer filling of wood until it comes within 2½ inches of the surface inside; an inner filling of oak similar in all respects to the outer is then placed on this, and by being driven firmly against the cement, forces it into all the interstices, and thus renders the bottom to within three inches of the plank under the orlop clamp, one solid mass. The fillings are then dubbed fair, and slightly caulked on one of their sides and well rammed and caulked on the other.

The plank of the bottom is fastened by one copper bolt in each butt, and by one treenail in each timber, and it receives additional security by the bolts passing through it which connect the diagonal frame, and of which we are about to speak. This trussed frame is composed of diagonal timbers, (or braces, Plate CCCCXCVIII. Fig. 1. B.) of horizontal pieces (C) and of trusses (D.) The diagonal timbers are first put in place, and lie at an angle of 45° with the timbers of the frame; they are coaked and bolted to those timbers as well as to the clamps over which they pass. The longitudinal pieces are then put in place, and finally the diagonal trusses: thus the whole combination forms a series of triangles. In the fore body, the keels of the diagonal timbers meet, and being connected with straps of iron, form breast hooks—those in the after body are united in the same manner and form crutches—accuracy of workmanship is highly desirable in the frame, as the closer the horizontal pieces and trusses are in contact with the braces, the less will be the alteration in the figure of the ship from arching or hogging.

Two additional keelsons are worked in midships, (Plate CCCCXCVIII. Fig. 3. H) one on each side: these extend about 33 feet and are placed at such a distance from the regular keelson, that the ends of the step of the mainmast may rest upon them, and by being coaked or bolted to the floors or cross pieces over which they pass, strengthen the ship in that part, and prevent alteration in form by the weight and stress of the mast downwards, or by the pressure of the water upwards, on those floors which lie in nearly a horizontal position.

The gun deck clamps and shelfpiece are got in place, the beams coaked and bolted thereto, the spirketting and waterings worked, and the chock placed under the shelfpiece; the beams of the gun deck are fastened by a forked knee, (Plate CCCCLXXXVIII. Fig. 5.)

The description which has been given will be sufficient to show in general terms the progression made in building ships, as it would be unnecessary to dilate upon a progress nearly similar through the several decks; suffice it to say, that the outside planking proceeds progressively with the inside. We shall proceed to give the methods of putting together and fastening the several parts.

Beams of the principal decks.—These, from their great length and size, are usually made in three pieces, the tops of the trees which make the two end pieces abut, and the deficiency of their scantling in the middle of the beam, is compensated by a middle piece which is coaked and bolted to the two end pieces.

Shelf pieces,—(Plate CCCCXCVIII. Fig. 1. *a*,) are coaked and bolted to the clamps and to the beams of the several decks; they may be considered as internal hoops, and by connecting the frame and beams preserve the form of the ship.

Chocks under shelf pieces.—(Plate CCCCXCVIII. Fig. 3. *c*.) Where the beams do not come directly over the ports, chocks are placed under the shelfpiece and immediately under the beams. Upon the chocks, the face of the iron clasp knee rests, and is bolted. Where the beams do come over the ports, they are attached to the ship by an iron hanging knee, fastened against the side at a sufficient angle of inclination to clear the ports.

Trussing between the ports.—Instead of all the planks between the ports being laid in a horizontal position, a diagonal truss, (Plate CCCCXCVIII. Fig. 1. C,) is placed against abutment pieces (F) between each port to prevent the arching of the ship. The trusses (in midship) at the neutral axis are double (G.)

Waterways, (Plate CCCCXCVIII. Fig. 3, *d*,)—These are rounded in front, are scored down on, and coaked and bolted to the beams; a rabbet is taken out on the fore side to receive the planking of the diagonal decks: this is sufficient depth to give a seam of 3 inches for caulking.

Decks.—The beams and half beams for the reception of the plank of the decks are so placed as to give the greatest degree of strength, but so disposed as to leave such openings as may be necessary for the hatchways, ladderways, rooms for capstans, &c.; the planking of the principal decks is then laid upon them in a diagonal direction, (Plate CCCCXCVIII. Fig 2;) the outer ends of the diagonal planking are received in the rabbet cut in the waterways, the inner ends abut against thick strokes running in a fore and aft direction in midships.

Sterns.—All ships of the line and frigates are now built with circular sterns: the disposition of the timbers is shown, Plate CCCCXCVIII. Fig. 4, and the galleries in Plate CCCCXCIX. Fig. 1.

The foregoing observations have been chiefly confined to the building of ships of the line. The difference in frigates is, that instead of working in the hold a diagonal framing of wood, iron trusses are laid on the timbers at an angle of 45°, and at a distance of 6 feet from each other; and over the joints of the timbers, and crossing these trusses, two strokes of thick plank are worked, Plate CCCCXCVIII. Fig. 7.

In sloops and smaller vessels their bottoms are also made solid as high as the line of water, and a thick stroke placed over the joints of the timbers in the hold. The beams are not in general kneed, but fastened by being coaked and bolted only to the waterways and shelf pieces; two or three iron knees, however, are usually placed under those beams on each side, which are nearly opposite to the mainmast, and the same number to those similarly situated with respect to the foremast.

Having given the general outline of the present improved practice of building ships, the reader is referred for more minute instructions to "The Elements and Practice of Naval Architecture, 3d edit."

When the fabric of the ship is finished, it then becomes necessary to put up magazines, cabins, and store rooms, as internal accommodations; the number, and generally the situation of these, depend upon the size of the ship, the service on which she is to be employed, and the quantity of stores and provisions necessary for the men to navigate her, and to fight her guns.

The internal conveniences and decorations are also to be attended to, such as the cathead for the anchors, the boomkins for the foretack, the channels for the reception of the dead-eyes for the security of shrouds and backstays, the stern galleries and headrails.

During the progress of building a ship, a variety of measures are resorted to for the purpose of preserving the materials from early decay, such as painting the surfaces of the timbers and planks which come in contact, injecting tar and lime into the bottom; but for these and other methods the reader is referred to a recent work, "Knowles on Preserving the Navy."

When the ship is ready to be launched into the water, sliding planks are laid upon blocks of wood on each side, at an inclination of $\frac{7}{8}$ of an inch to every foot of their length, or at an angle of nealy 4° 10′; these planks are usually laid straight, but a slight curvature is preferred by some builders. The distance of these sliding planks from the keel on each side depends upon the form of the body; but as a general principle, it may be considered as one-sixth the extreme breadth of the ship. Ribbands are fitted on the outer edges of the sliding planks to keep the cradles in their places. A combination of large pieces of timber, called bilgeways, is then placed upon the sliding planks, and a cradle fitted thereon to the form of the ship. This cradle is attached to the slip by a shore on each side, called dog-shores, lying at a small angle of inclination. A short time before the ship is to be launched, the bilgeways are canted out, and the sliding planks payed over with a composition made of soft soap, oil, and tallow. When the cradle is replaced and properly fixed, the shores against the sides and stern of the ship are taken away, the blocks under the keel split out, and the dog-shores removed; and thus, being left without any impediment, the ship glides down the inclined plane into the water.

Scholium.

Soon after the introduction of the diagonal system, considerable doubts were entertained by many practical men respecting the proper disposition of the braces and trusses; some asserting that the arrangement given to them by Sir Robert Seppings was just the reverse of that which ought to have been. To obviate any objection on this head, we extract from a paper in the Philosophical Transactions for 1818, an account of an interesting experiment, performed by Sir Robert Seppings, to prove the truth of his mechanical arrangement of the trusses and braces.

"Early," says he, "in the year 1817, the Justitia, an old Danish seventy-four gun ship, was ordered to be broken up on account of her defective state; and having observed her to be considerably arched, or hogged, I determined, notwithstanding her age and defective state, to apply the trussing principle to a certain extent, with a view to observe what effect it would produce on a fabric reduced to so weak and shaken a condition.

"The officers of the yard were directed to place sights on the lower and upper gun decks prior to her being taken into dock; and to ascertain, when she grounded on the blocks, how much she had altered from the state in which she was when afloat. They were then to place a certain number of trusses in the hold, some in the forepart of the vessel inclined *forward* at about an angle of forty-five degrees, and others in the after part of the vessel inclining *aft* at the same angle. Others were also to be placed at right angles to the former, and so as to act against the beams of the deck. In the ports also, other trusses were introduced, those in the ports forward, inclining forward in an angle of 40°, and those in the midships aft, at the same angles, but in an opposite direction. (A drawing of the arrangement of the trusses, &c. may be seen in the part of the Philosophical Transactions referred to.) As it was uncertain where the centre of fracture would take place, a few of the port holes about the centre of the ship had trusses introduced into them in *both* directions. Wedges were applied to the heels of the trusses to set them tight. The ship being thus *partially* trussed, the water was let into the dock, and the ship floated out of it into the basin, where she was to lay one hour, when a committee was to examine the sights, and ascertain how much the ship had altered; and again, what change had taken place in twenty-four hours after floating. This being done, the trusses were to be disengaged in as short a time as possible, in order to observe whether the effect of their removal would be instantaneous or gradual."

The following is an extract from the report of the Committee.

"When the ship was in dock, on blocks perfectly straight, she came down in the midships, by the sights placed on the gun deck, *two feet two inches and a half*; and by those on the upper deck, *two feet three inches and a quarter*: and when undocked, with the trusses complete and in their places, she hogged, or broke her sheer, by the sights on the gun deck, *one foot two inches*; and by those on the upper deck *one foot two inches and five eighths*: and at the expiration of twenty-four hours she had hogged, or further broke her sheer, *two inches and five eighths*, and then appeared stationary and completely borne by the trusses.

We then proceeded to take away the trusses in the hold, and when they were wholly disengaged, she further hogged, or broke her sheer, *six inches*. We next proceeded to take away the trusses in the ports, and when they were wholly cleared, she dropped at the extremities, or further hogged, *three inches and a half*, and was in the same position when tried twenty-four hours after.

We further beg to state, that the whole of the trusses alluded to as placed at right angles to the first introduced, *slackened as the ship floated* from the blocks, and became *short from half an inch to three inches and a half, and partook of no part of the pressure*; which, in our opinion, clearly proves that the direction in which Sir Robert Seppings has applied his diagonal frame is correct, as also the great utility of the trussing system; for although the ship, from her very defective state, was much against so severe an experiment, it has proved to us its good effects most satisfactorily; for many of the trusses in the ports *forced the timbers three eighths of an inch within the ends of their covering planks*, thereby lessening their effect from what it would have been if the ship had been of a sound texture; yet on a ship in this state, *the trussing between the ports alone*, after those in the hold were wholly disengaged, had the effect of sustaining the immense pressure of both ends of the ship in her worst position, and prevented her from breaking, which she otherwise would have done, from three to four inches, and which she actually and *immediately* did on their being disengaged."

This statement of the Portsmouth officers, says Sir Robert Seppings, will, I trust, be considered conclusive as to the benefits to be derived from the princi-ple of trussing in the construction of ships *though it was only applied from the keelson to t* *in the hold, and not to the ribs or frame of th* is the case when ships are regularly built on this system, yet it sufficiently establishes the soundness of the principle.

When the Justitia first floated, continues Sir Robert, after being partially trussed, as described, the noise occasioned by the pressure on the trusses, is stated to have been *truly terrific*, until she was fairly settled on them. The disengaging them also caused a similar crash.

Very recently, Mr. Harvey has shown from theoretical principles, that Sir Robert Seppings's disposition of the diagonal frame is consistent with the soundest principles of mechanical truth. His investigation, originally published in the 42d number of the *Journal of the Royal Institution*, is here given.

Mr. Harvey introduces his subject with the well-known mechanical principle, viz. that if through the point in which the sustaining forces meet, a line be drawn to represent the measure and direction of the straining force, and on it a parallelogram be constructed, as a diagonal, having its sides parallel to the sustaining forces; then if the remaining diagonal of the parallelogram be drawn, and through the point where the sustaining forces meet, another line parallel to the same, all the parts of the framing on *the same side* of this line, as the straining force, will be in a state of *compression*, and all those on the *other side* of the same line in a state of *extension*.

Mr. Harvey illustrates the application of this mechanical principle by two diagrams as follows: In Fig. 7. Plate CCCCXCV. let AB and AC represent two of the braces or ties of a system of a diagonal framing, and GD, DF, HE, EF, corresponding trusses. Let also GH, DE, and BC denote the longitudinal timbers of the same system, and F the fulcrum on which the whole is supported. Then if we apply the mechanical principle in the first place to the brace AC, and the longitudinal timber BC at the point C, where these timbers may be supposed to meet, let the vertical line CI be drawn to represent the measure and direction of the straining force operating at that point. On CI as a diagonal, let the parallelogram C *a* I *b* be constructed, having its sides in the directions AC and BC of the longitudinal axes of the timbers selected for consideration. Draw the other diagonal *a b* of the parallelogram, and through C, where the vertical force is supposed to operate, draw *d e* parallel to *a b*. Then, since the longitudinal timber BC is on the *same* side of *d e* as the straining force CI, it will, by the principle referred to, be in a state of *compression;* and the brace AC, being on the *opposite* side of the same line, will be in a state of *extension.*

To apply the same principle in the second place to the brace AC, and the truss FE, let the straining force be supposed to be applied at E, and EK to denote its measure and direction. Complete the parallelogram E *f* K *g*. Join *f g*, and through E draw *h i* parallel to *f g*. Then the truss FE being on the *same* side of *h i* as the straining force, EK, will be in a state of *compression:* and the brace AC being on the *opposite* side of the same line, will be in a state of *extension* as determined in the preceding case.

To apply the mechanical principle in the next place, to the brace AC or AB and the longitudinal timber DE, let the straining force be allowed to act at D, and let DL be its measure and direction. Complete the parallelogram D *k* L *l*, and join *k l*; and through D draw *m n* parallel to the last mentioned line. Then the longitudinal timber DE being on the *same* side of *m n* as the straining force, it will be in a state of *compression*, and the brace AB or AC, as before determined, in a state of *extension.*

Fourthly, Let the parts now to be selected, be the longitudinal timber GH and the truss HE. Then if the straining force be applied at H, let HM denote its measure and direction; and on it as a diagonal, let the parallelogram H *o* M *p* be constructed, having its sides coincident with the directions of the timbers proposed: join *o p*, and through H draw *q r* parallel to it. Then since the truss EH is on the same side of *q r* as the straining force, it will be in a state of *compression:* and the longitudinal timber AH being on the *opposite* side of the same line, will be in a state of *extension.*

Hence it appears that the resultant of the various forces acting on the diagonal frame proposed will operate so as to *extend the braces* AB and AC *and the longitudinal timber* GH; but on the remaining parts of the frame, viz. the *trusses* GD, DF, HE, EF, and the *longitudinal timbers* DE, BC, the effect will be to produce *compression:* agreeing with the experimental conclusion of Sir Robert Seppings, that the frame with this disposition of the braces "comes more in contact by the pressure."

Let us now endeavour to estimate the effect of a similar system of forces, on a system of framing whose braces and trusses are disposed in *opposite* directions to those of the preceding investigation. For this purpose, let the first application of the lemma be to the longitudinal timber BC, and brace AC, Fig. 8, A being the fulcrum; and let the point C be that to which the straining force is applied. Suppose CI to be its measure and direction, and complete the parallelogram C *a* I *b*. Join *a b*, and through C draw *d e* parallel to that diagonal. Then since the brace AC is on the *same* side of *d e* as the straining force, it will be subject to *compression*, contrary to the effect produced in the former case. But the longitudinal timber BC, like GH in the former figure, will undergo *extension.* In the next place, let the straining force be supposed to be applied at E, in order to estimate its effects on the brace AC, and the truss FE; and let EK be its measure and direction. Complete the parallelogram E *f* K *g*; join *f g*, and draw *h i* parallel to it through the point of application E. Then the brace AE being *below* the line *h i*, will undergo *compression* as before; and the truss FE being *above* the same line will undergo *extension.*

In the *third* place, let the straining force be applied at D to produce an effect on the brace BA and the longitudinal piece DE, and DL be its measure and direction. Complete the parallelogram of force D *k* L *l*. Join *k l*, and through D draw *m n* parallel to *k l*. In this case, therefore, the brace DA being *below m n* must undergo *compression*, and the longitudinal timber DE being *above* the same line, must undergo *extension.*

Fourthly, Let the straining force be applied at H, to estimate its effect on the truss EH, and the longitudinal timber GH, and let its measure and direction be HM. Complete the parallelogram of forces, H *o* M *p*, having its sides in the axes of the timbers proposed. Draw the diagonal *o p*, and parallel to it, through H, the line *q r*. Hence it appears that the truss EH, being *above* the line *q r*, must undergo *extension:* and the longitudinal timber GH, being *below* the same timber, must undergo *compression.*

With this disposition of the timbers, therefore, it appears, that the forces operating on the frame will produce a *compression of the braces BA, CA*, and of the *longitudinal timber* GH; but on the remaining parts of the frame, viz. the *trusses* BD, DA, CE, EA, and the longitudinal timbers DE, BC, the effect will be to produce *compression*, agreeing also with the experimental conclusion of Sir Robert Seppings, that on the application of a straining force, the trusses and middle longitudinal piece "will be immediately disengaged and fall out."

The preceding results may be conveniently arranged in the following table:

	Nature of the strain operating on the timbers				
	Braces.	Trusses.	Upper longitudinal piece	Middle longitudinal piece.	Lower longitudinal piece.
With the braces in the *forebody inclined aft*, and those in the *afterbody inclined forward* as in Fig. 7.	Extension.	Compression.	Extension.	Compression.	Compression.
With the braces in the *forebody inclined forward*, and those in the *afterbody inclined aft* as in Fig. 8.	Compression.	Extension.	Extension.	Extension.	Compression.

The primary object of the diagonal framing is to prevent arching; and if we suppose AF, in both figures, to represent the natural line from which the arching proceeds towards both extremities, it is evident that it is the mechanical combination represented in Fig. 7. which can alone prevent it. For since A, in that figure by the hypothesis, is one of the *neutral* points of the system, it may be regarded as fixed, and the tendency of arching being to depress the point H, C, and G, B, the effect on the braces AC and AB will be precisely similar to the weights applied in the preceding investigation; that is, to produce *extension*, and which is effectually provided for by the fastenings. The effect, moreover, brought at the same time into action by the trusses, in consequence of the disturbing force, is to resist, by the whole longitudinal strength of their fibres all tendency to alteration of form; so that the effect exerted to depress the point C, is at once resisted by the fastenings appertaining to the brace AC, and to the longitudinal strength of the fibres of the truss proceeding from the unchangeable point F. The point E becoming, in this point of view, fixed, the action of the force which tends to depress the point H, in common with the point C, is resisted by the fastenings of the longitudinal timber AH, and by the longitudinal resistance of the fibres of the truss EH; so that, provided the fastenings of the braces and of the upper longitudinal timber are sufficient, and the abutments of the trusses and of the middle longitudinal timber are also proper, all tendency to arching will be resisted in proportion to the perfection of the materials, and the excellence of the workmanship.

But by referring to the converse disposition of the braces, as represented in Fig. 8, it appears, from the preceding investigation, that the braces AC and AB are subject to *compression*. And since the point A is by the hypothesis, the neutral or fixed point, the effect of the compression of the brace AC must be to *depress* the point C, and thus to promote the tendency to arching. Nor is this tendency to lower the point C prevented by the action of the truss FE; since the point F being fixed by the supposition, the tendency to *extension* which takes place in the truss must tend to lower the point E, and thus to promote the further declension of the point C. The point E being thus depressed, must add its effect to the extending force called into action in the truss EH, and thus produce a declension in the point H. Hence the whole effect of the disturbing force is to *lower* every part of the frame from C to H, and thus to promote the arching of the vessel. Hence the superiority of the present system of diagonal framing becomes apparent, and the advantages derived from it are demonstrated by the small alteration of form which ships now undergo in the act of launching.

ON THE CONSTRUCTION OF SHIPS IN THE MERCANTILE NAVY.

It is remarkable that most of the investigations offered to the public notice respecting shipbuilding have an especial reference to the construction of ships of war, their ingenious authors seeming to overlook the great variety of vessels which constitute our commercial marine. That the country is deeply interested in whatever relates to commerce, that great source of our national wealth, there can be no question: and when we know that the tonnage of British shipping belonging to the ports of the united kingdom, amounts on an average to nearly a million and a half annually, transporting from thence the varied products of British industry and skill to every quarter of the globe, it would be unpardonable in an article on shipbuilding, not to make some brief allusion to a subject of so important a kind.

There is a serious and important defect in the present construction of mercantile ships, as regards the putting together of their ribs or frames, and the general arrangement of the materials.

In forming the frames or ribs, *half the timbers only are united so as to constitute any part of the arch*; every alternate couple only being connected together, the intermediate timbers, termed fillings, being entirely unconnected with each other, resting only on the outer planking, without contributing in any degree towards its support. It must be evident that ships so constructed can by no means possess equal strength with such as have the whole of their timbers formed into uniform frames or arches.

This loose, dangerous, and very imperfect mode of shipbuilding, is, according to Sir Robert Seppings, peculiar to the English merchant shipbuilder; and we know even that it is only in latter years that the same system of building has been abandoned in the king's dock yards, while the preferable system of connecting the ribs was common to other maritime powers.

The principle of uniting the frames, lately introduced in the construction of ships of war, might without doubt, be advantageously introduced into the mercantile navy; a system which would communicate to the ships of our commercial marine much additional strength and increased durability, *without adding to the expense of building*.

But the present mode of joining together the several pieces of the same rib, is open also to the heaviest objections. The method adopted is by introducing a third piece, technically termed a *chock* or *wedge piece*, as in Fig. 1. Plate D. of which pieces the number amounts to upwards of 450 in a 74 gun ship, and to not less than that number in an Indiaman of 1200 tons, and to which class of ships the subsequent drawings to be referred to have an especial reference. Of these chocks, not one in a hundred is ever replaced on the general repair of a ship; for they are not only found defective, but very generally to have communicated their own decay to the timbers to which they are attached. Besides this the grain of the rib pieces being much cut to give them the curvature required, contributes in a very considerable degree to the general weakening of the fabric. That they occasion a great consumption of materials is very obvious, as the ends of the two rib pieces must be first cut away, and then replaced by the chock.

The introduction of chocks was done with the view of obtaining that curvature which is so necessary in the formation of a ship, when crooked or compass timber became scarce, as may be seen by a reference to Fig. 2. which describes the shape of a piece of timber in the converted form; and by which also it will be perceived that the introduction of the chocks assists in obtaining the required curve.

The frames of a mercantile ship, on the present mode of building, before they are placed and united to each other, may be seen in Fig. 3. with their chocks or wedge pieces. To the evils already stated of the present practice, may be added that of imperfect workmanship, so that the surfaces of the chocks are seldom in contact with the surfaces of the timbers. The ends of both are moreover frequently reduced so thin, as to split by the fastenings that are necessary to secure the planks to the ribs; and thus the ship, in the event of grounding, or even in the ordinary act of rolling, derives little support from timbers united only in fact by two narrow edges.

Another great defect arising out of the present plan of constructing mercantile ships is, that the ends of the lower ribs or timbers, commonly termed the futtocks, Fig. 3. B, are not continued across the keel C, so that no support is given in a transverse direction when the ship touches the ground: nor any aid to counteract the constant pressure of the mast. This great sacrifice of *strength* and *safety*, is made for no other purpose than that of giving a passage for the water to the pumps.

The floor timbers, which by this mode of construction are the only timbers which cross the keel, are also weakened for the same purpose, as shown at D in the figure last quoted. This mode, moreover, makes the conveyance of the water very uncertain, since the passage is not unfrequently choaked: and the pumps, from its not being practicable to continue them sufficiently down, always leave from six to eight inches of water in the ship; so that these compartments constantly contain a certain quantity of putrid bilge water, offensive and injurious to the health of those on board.

The deficiency of strength causes also an alarming insecurity in the plank of the bottom, termed the garboard strake, as shown at E; and which consequently is in no other way connected with the general fabric, than its connexion with the keel at F, and a slight security at G. Hence it is obvious, that in the event of the keel being disturbed, the garboard strake, from its being attached to it, must share the same fate as the keel, and in that case the loss of the vessel would be inevitable.

To obviate these very serious defects, and to do that for our mercantile marine which he had already so successfully accomplished for ships of war, Sir Robert Seppings laid before the Royal Society in March 1820, a highly important paper, and which was printed in the Transactions of the same year. The principle may be comprehended by a reference to Fig. 4. in which it will be seen, *that the component parts of each rib are of shorter lengths and less curvature, and consequently less grain cut: that they are more firm and solid by the substitution of coaks or dowels, for chocks or wedge pieces: and that the mode of connecting the lower timbers is better adapted, in the event of a ship grounding, to give support and strength to the fabric, as will appear by the line marked H.*

That the frame of the Thunderer, (now Talavera,) built on this principle, is superior in point of strength, says Sir Robert Seppings, to a frame constructed on the common system, is fully established by a report from the officers of his majesty's yard at Woolwich to the Navy Board, who directed them to compare the strength of the frames so united with those of the Black Prince, constructed in the usual way with chocks or wedges.

In alluding to this interesting and important comparison, Sir Robert remarks, that "*the frame of the Thunderer was composed of small timber, hitherto considered applicable only for the frames of frigates.*" "I was prompted," says this ingenious constructer, "to attempt the introduction of the plan on which she is built, from there being a surplus store of small timber in the yard; and from a conviction, *that a well-combined number of small timbers might be made equal, if not superior, both in strength and economy, to the large, overgrown, and frequently grain-cut materials, made use of in constructing the frames of large ships: and the result has shown the correctness of the principle;** the adoption of which cannot fail to prove of great national advantage, in *the application of sloop timber to the building of frigates, and of frigate timber to ships of the line,* whenever larger timber cannot be procured. On this principle, also, may frigates and small ships of war, or merchant vessels, be built of straight fir, without the assistance of oak or elm, which were formerly employed to give the necessary curvature of the sides." The principles here laid down by Sir Robert Seppings, are of vast importance, and we earnestly hope will speedily and generally be adopted.

As it respects the general safety of the ship, it will be seen by a reference to Figure 5, Plate D. and Plate DI. that the timbers uniformly cross the keel; that the frame of the ship is filled so as to form one compact body to the height marked K; and that only certain internal strakes of planks, or thick stuff, as it is termed, are introduced, which are those on the joints of the timbers, for the purpose of giving strength where every alternate timber necessarily joins, as shown at L. The rest of the inner planking may be omitted, and dunnage battens brought in a perpendicular direction upon the timbers *between* the plank, as shown at M, forming regular spaces between each, as is usual at present, *upon* the plank; thereby giving an increase of stowage in proportion to the thickness of the plank omitted. Water courses, as shown by dotted lines at N, are to be left in the joints of the timber under the plank, for the purpose of conveying the water to the pumps: which, by this plan, will reach below the water, instead of being some inches above, as is the case with the present mode, before described. Consequently, by the proposed system, no stagnant water will remain; and farther, the limber passage, or water course, will be one smooth uniform channel, which can be cleared with ease, should it be required, whenever the hold is unstowed; whereas at present it is inaccessible in places, and forms compartments for putrid water, without there being any means of removing it.

It is obvious that a ship constructed on this principle, may sustain the loss of certain planks of the bottom, and also the keel, (which has frequently been found to have happened to ships of war on their being taken into dock,) and still reach the place of her destination, when the loss of *either* would be the de-

* "A just economy of materials should be one of the first objects of the builder's attention, and this desirable object is to be obtained only by judicious combinations of the materials to be used."—See the valuable work of Mr. Tredgold on the Elementary Principles of Carpentry.

struction of a ship built on the present mode. It will be evident also, that a ship constructed as now recommended, possesses greater stowage and more space for leakage than by the old plan, by the omission of the useless inner planking, and by laying the kentlage on dunnage, leaving a space for the water, which was formerly occupied by the inner lining. This dunnage in the bilge may be found in the iron kentlage, and thereby serve as ballast, for which it is well calculated from its situation, and by its occupying a space heretofore forming part of the fabric of the ship, will give an increase of stowage, as before stated.

The best method of closing the openings between the timbers, is by filling the intermediate space with pieces of wood, about three inches in depth, of such lengths as the inferior conversions will supply, abundance of which may be procured from the offal. These fillings are to be well caulked, after which the exterior plank is to be brought on. When the works are going on within board, similar pieces are to be fitted internally, and afterwards taken out for the purpose of filling the spaces between the pieces so fitted with a mixture of Parker's Roman cement and drift sand, in the following proportions, viz.

Parker's Roman cement, $\frac{2}{3}$

Drift sand, . . $\frac{1}{3}$

previously paying the opening well with coal tar. Where there is sufficient space, a brick, or part of one, may be introduced, provided there is room for cement between it and the timbers. When filled in to within about two inches of the surface of the frame, the pieces of three inches already fitted and taken out, are to be well driven in and caulked, and by so doing, no space will be left unoccupied. If considered desirable, these pieces may be driven below the surface of the timber, thereby leaving water courses to convey the leakage to the pumps in channels. And prior to launching or undocking of ships built on this principle, it has been the practice to inject the part filled in with mineral tar by means of a simple forcing pump, boring holes in the joints of the timbers for the introduction of the pipe. By following this method the air will be excluded, which, as experience has shown, tends much to the durability of the fabric. If what is here recommended be attended to, says Sir Robert Seppings, and mercantile ships were built under roofs, as ships of war now are, durability would be obtained in addition to safety from the mode of their construction.

The beams are to be attached to the sides, as shown at O, Plate D. Figure 5, rendering wood knees unnecessary, and requiring only a small number of those of iron.

Plate DI. Figure 1. marked P, describes the old principle of framing the stern with transoms. Q represents the new principle, with timbers similar to the bow, omitting the transoms below the wing or upper transom; and by introducing the new principle on which the floors are made, the necessity of using valuable compass, or crooked timber, hitherto required and with difficulty procured for these purposes, is avoided. Uniform support will thus be given, and also an increase of room for stowage.

In large mercantile ships above 500 tons, Sir Robert Seppings would recommend that plate iron be laid diagonally, as shown in Plate DI.

The principle thus recommended will cause a decrease in the consumption of materials, and the difficulty of procuring the necessary curvature will be obviated. It also affords protection from worms externally, and vermin internally. Leaks may be more easily discovered and stopped than by the old method; and in point of additional strength there can be no doubt. If farther proof were required, Sir Robert Seppings refers to the case of the Malabar of 74 guns, built at Bombay, and which arrived at Portsmouth, loaded to her upper deck with timber, and during her passage encountered four heavy gales of wind, without showing a symptom of weakness, as will appear by the following extract from the survey made by the officers of the Plymouth yard, on that ship, by order of the Lords Commissioners of the admiralty.

"When we consider the nature of the lading that this ship has brought home, with the temporary security to the beams of all the decks, except the orlop, and that on her passage she encountered four very severe gales of wind, it must, we presume, be very gratifying to your honourable board to find, that she does not indicate any past symptoms of weakness or straining in any part."

This ship had no other attachment for her beams than the internal hoops and thick water ways; the remainder of her security, the iron knees, being omitted (from the difficulty of procuring them in India) until her arrival in this country; thus supporting her cargo without the aid of knees, either of wood or iron.*

Having delivered these general observations on the best method for constructing the hulls of merchant ships, we close this part of the article with a few observations on the proportions of their masts and yards.

Chapman remarks on this important subject, that the area and moment of the canvass for merchant ships ought to be determined in the same manner as for ships of war, although the circumstance of their taking cargoes of variable density must occasion a corresponding variation in their moment of stability. There may, nevertheless, be supposed at all times a fixed point for the centre of gravity of the ship and its lading, from which the moment of the canvass may be calculated.

It is most usually the case to proportion the height of the masts to the breadth of a ship, and the length of the yards to the length of the same; and from which it may be inferred, that ships of the same length and breadth, but possessing different degrees of stability, must have the same extent of canvass; whereas the extent of canvass should rather seem to be proportioned to the stability. True as this rule may be for armed ships, there may be reasons of a very strong kind why the same principle should not be followed in merchant ships.

When it is considered, says the celebrated Swedish

* We regret that some circumstances, connected with a patent obtained by Sir Robert Seppings for constructing masts on a new and peculiar principle, prevent us from furnishing any account of it to our readers. An account, however, of the method of construction may be shortly expected from the pen of the inventor.

architect, that the weight of the anchors of a ship is proportional to the length and breadth, or to the square of the breadth, and that the act of weighing the anchors requires a certain number of men, as also the working of sails of a certain size; that large sails require a numerous crew, and that numerous crews are expensive to maintain; it appears that, for a merchant ship it is advantageous to have as small a crew as possible; or that it is most consistent with good management, that the number of the crew should be suited as well to the magnitude of the sails as to that of the anchors.

Hence it appears, that it is the number of the crew which confines the area of the sails to definite limits.

Let us inquire, for a moment, how far the ordinary proportions of masts and yards are proper. Suppose two ships of the same length and breadth, and having, according to the usual practice, the same extent of canvass, but that one of the vessels carries sail better than the other; the usual remark in such a case is, not that *this* has too much or *that* too little canvass, but that the former has greater stability than the latter. Hence we might conclude that it would be better to effect some alteration in the form of the sails, or to make them smaller with relation to the stability, (preserving in other respects the ordinary proportions.) than to augment the number of the crew, in order to be able to use a greater quantity of canvass. At the same time, however, it may be remarked, that when the surface of the sails, according to the usual proportions, is too great with respect to the stability, it should rather be an object to place the parts of the lading which possess a greater specific gravity lower, than to diminish the area of the canvass, particularly if the number of the crew cannot be decreased on account of the anchors.

Moreover, it is worthy of remark, that in different circumstances the same area of canvass may be as proper for a vessel of greater stability, as for one of less. In one case, the surface of the sails may be increased by means of studding sails and stay sails, and diminished in the other, by taking in reefs according to the state of the weather. Hence there is great reason, continues Chapman, to use the rule according to which the masting is proportioned for merchant ships, as that gives most nearly those proportions for the masting which have already been found by experience to be the best. So that the moment of stability, according to which large ships have masts higher, and small ones lower, than the result of the usual rule, will not serve to found thereon the proportions of masts and yards for merchant ships.

As the breadth of ships has the greatest influence on the stability, the lower masts and top masts should be proportioned to the breadth, whence not only the height of the sails, but also the altitude of their common centre of gravity, will be in proportion to the said breadth. With respect to the breadth of the sails, or what is the same thing, the length of the yards, it should be proportioned to the length of the ship, and from which it follows, that the moment of the sails will be as the square of the breadth, multiplied by the length. Small ships will, therefore, have a greater moment of canvass, in proportion to their stability, than large ones; and it is a received practice in small ships to increase the height of their lower masts still more, but at the same time to diminish the altitudes of the top masts. If we assume the breadth of a trading ship equal to B, the height of its main mast, according to Chapman will be $3.23\ B^{\frac{11}{12}}$; and the height of the main top mast, reckoning from the upper side of the cross trees, that of the main mast being denoted by L, will be $\frac{L^{\frac{11}{10}}}{2.73}$ for frigates, and $\frac{L^{\frac{11}{10}}}{2.84}$ for barks. By a reference to Fig. 1, Plate CCCCXCIV, the line BNN will be found to represent the height of the masts in the proportion of the element $B^{\frac{11}{12}}$. The length of the bowsprit, outside the stem, for frigates, is 1.15 B, and for barks 1.1 B, where B denotes, as before, the breadth of the ship.

That ships may be well rigged, it is necessary, in the first place, that the fore stay and main top mast stay should be in a right line, and, in like manner, the main and mizen top mast stay. The fore stay may end on the bowsprit, between one-third and two-fifths of its length from the small end: secondly, that the top sails should be of similar figures, or at least, that their sides should be of the same cut: thirdly, that when the ship is seen, at one or other of the extremities, the shrouds and the breast back stays should appear parallel: this depends partly on the breadth of the channels, which ought to be regulated in a manner conducive to this end. To accomplish it, the length of the head of the main mast, from the under side of the trestle trees, which is $\frac{5}{36}$ of the length of the mast T, the cap of the fore mast should be lower than that of the main mast, by a quantity $2.22\ T^{\frac{1}{3}}$ for frigates, and $2\ T^{\frac{1}{3}}$ for barks. The cap of the mizen mast should be on a level with the main top.

If the length of the main top mast be denoted by S, the length of the mizen topmast will be $1.3\ S^{\frac{6}{7}}$ for frigates, and $1.316\ S^{\frac{6}{7}}$ for barks, supposing the length of the pole to be in the same proportion, as for the other top masts. If it be longer, that difference is added.

The head of the mizen mast ought to be $\frac{3}{4}$, and that of the fore mast $\frac{9}{10}$ of that of the main mast. The length of the fore top mast should also be $\frac{9}{10}$ of that of the main; the heads of these masts $\frac{1}{9}$ or $\frac{2}{17}$ of their length. The length of the top gallant masts to the stop should be 0.54, the length of the top mast. The length of the main yard $0.52 \times$ the length of the ship from the stem to the stern post for frigates; and the main top sail yard $0.79 \times$ the length of the main yard. For barks, supposing their extreme length L, the length of the main yard will be $0.6\ L^{\frac{20}{21}}$: the length of the main top sail yard $0.81 \times$ the length of the main yard. The main top gallant yard $= 0.7 \times$ the length of the main top sail yard. All the yards of the fore mast are $\frac{9}{10}$ of those of the main mast.

Again, Chapman informs us, that the proportion of the mizen top sail yard to its mast, is equal to the proportion of the main top sail yard to the main top mast. The cross jack yard = 1.22 the length of the mizen top sail yard for frigates, and = 1.18 × this length for barks. The sprit sail yard = fore top sail yard; the sprit sail top sail yard = fore top gallant yard. The girth of the yard arms is $\frac{1}{11}$ of their length for the lower yards, and those of the top gallant yards; but $\frac{1}{7}$ for the top sail yards.

The distance of the centre of gravity of the fore mast from the perpendicular at the stem is $\frac{4}{31}$ of the length. The centre of the main mast is $\frac{2}{31}$ behind the middle of the ship. The distance of the centre of the mizen mast from the perpendicular at the stern = 0.182 × by the length of the ship.

The main mast should rake aft one foot in thirty; the mizen mast double the rake of the main mast; the fore mast should be perpendicular, and the elevation of the bowsprit above the horizontal plane, should be about four feet for frigates, and three for barks, in a length of seven feet.

With respect to the diameter, experience has shown that if the respective lengths of the main mast, main yard, and main top mast in feet be denoted by L, R and S, the diameter of the main mast in inches will be $\frac{LR^{\frac{1}{3}}}{13}$; that of the main top mast $\frac{S^{\frac{11}{10}}}{4.68}$; the diameter of the fore mast $\frac{1}{20}$ less than that of the main mast; and that of the fore top mast $\frac{1}{20}$ less than that of the main top mast. The diameter of the top gallant mast = 0.3 × their length reckoning to the stop. The diameter of the bowsprit should be a mean of the diameters of the main and fore masts; the diameter of the jib boom $\frac{3}{4}$ that of the main top mast; the diameter of the mizen mast $\frac{2}{3}$ that of the main mast; and the diameter of the mizen top mast $\frac{2}{3}$ that of the main top mast.

Again, the diameter of the main yard, and that of the fore yard in inches = 0.25 × length of the yard; that of the top sail yards = 0.23 × also by the length of the yards; that of the top gallant yard = $\frac{1}{6}$ of their length. The diameters of the sprit sail yard, and cross jack yard = 0.21 the length. The diameter of the sprit sail top sail yard = that of the main top gallant yard. The diameter of the mizen peak is an inch for four feet in its length. The studding sail booms have two feet greater length than half the yard, and their diameter in inches is $\frac{1}{5}$ or $\frac{1}{6}$ of their length in feet.

The depth of the main trestle trees in inches is the fourth of the height of the top mast in feet, less half an inch; the thickness of the fore trestle trees is $\frac{1}{15}$ less than that of the main trestle trees, and the mizen $\frac{3}{5}$ of the main; the thickness of the top mast cross tree is $\frac{3}{7}$ that of the trestle trees of the respective tops. The breadth of the said trestle trees and cross trees is $\frac{5}{7}$ or $\frac{3}{4}$ of their depth. The thickness of the caps is $\frac{4}{5}$ of the diameters of the top mast.

As the masts and yards taper towards their extremities, it is not only necessary to know their greatest diameters, but also the ratio in which those diameters are diminished, to give them the form which experience sanctions as best adapted to resist strains to which they are exposed. The interval between the greatest and least diameters being divided into four parts, the diameter at each of the divisions should be as follows: The lower masts are found to be well proportioned when their diameter at the place of the trestle trees is one-eighth less than at the deck. So that the diameter at the deck being 128, at the first division it will be 127, at the second 124, at the third 119, and at the fourth 112. The thickness within the trestle trees should be $\frac{4}{5}$, and above at the head, $\frac{5}{8}$ of the diameter at the deck. The top masts should have $\frac{1}{5}$ less diameter under the cross trees than at the cap of the lower masts. So that the diameter at the cap being 80, at the first division it will be 79, at the second 76, at the third 71, and at the fourth, below the cross trees 64. The thickness within the cross trees and above at the head will be $\frac{5}{9}$ of the diameter at the cap.

If the greater diameter of the lower and top sail yards be 27, at the first division it will be 26, at the second 23, at the third 18, and at the end 11. If also the greater diameter of the top gallant yards be 32, at the first division it will be 31, at the second 28, at the third 23, and at the yard arm 16. The bowsprit has usually at its extreme end a diameter only half that at the gammoning. If the diameter at the latter part be for example 60, at the first division it will be 59, at the second 55, at the third 46, and at the fourth 30. Brigs and snows have their fore masts and its appendages, as well as the bowsprit, of the same proportions as frigates. But the height of the main mast of brigs ought to be such, that its top may be on a level with the cap of the fore mast, the head of the main mast being equal to the head of the fore mast. The main top mast should be of the same length with the fore top mast, and the main yard and main top mast yard the same as the fore yard and fore top mast yard. In snows, the main mast is a mean between the masts of a frigate and brig, and so also the top masts; but the main yard and main top sail yard are of the same dimensions as those of frigates.

East India ships should have the length of the main mast = 2.43 × their breadth; the length of the main top mast = 0.586 × the length of the main mast; the length of the main yard = 0.54 × the length of the ship; the top sail yard 0.8 × main yard; the main top gallant yard 0.7 × top sail yard, and the mizen top mast $\frac{3}{4}$ of the fore top mast. The cap of the fore mast is $\frac{2}{5}$ of the length of the head of the main mast lower than the cap of the main mast, and the cap of the mizen mast is on a level with the main top.

The masts and yards are first proportioned, after which a draught of them is made, including the rigging and sails. Their moment is then finally compared with the moment of stability, which will determine the masts and yards suitable to the moment of the sails.

Such are the observations of Chapman on the proportions of masts and yards for merchant vessels—proportions deduced of course from Swedish vessels, but which nevertheless merit much of the attention of the English shipbuilder. And in quoting for the last time the name of this learned and indefatigable man, we would impress most earnestly on the attention of our readers his important investigations, founded as they are on a large and extended experience. To the young naval architect we would hold him up as a model worthy of the closest imitation.*

ON STEAM VESSELS.

The application of steam to the propelling of vessels on the ocean, is likely to produce as great a revolution in warfare as the first introduction of cannon; and its general influence on navigation will claim in its ultimate consequences, a rank almost equal with the splendid discovery of the compass. As an instrument of war, it is destined most likely to change the entire aspect of military operations, and to give to its energies a more fierce and terrible character. In a calm, a ship of war impelled by steam, will possess a decided superiority over an opponent navigated only by sails; and battles that sometimes remain undecided, on account of the failure of the wind, would by the sure and certain energies of steam, be speedily accomplished. Coasts, rivers and harbours, that, according to the ancient plan, were considered as secure, will by this new application of vapour, be assailed and defended by them. The system of warfare will be entirely altered, and perhaps the steam gun will lend its aid in assisting in the work of human destruction. A modification of the energies, however, that render it so terrible in war, will assist the milder and more beneficent purposes of commerce, and direct the steps of civilization into regions now debased by gloom and superstition. Thus it is that art, as well as nature tends to preserve a balance in all its operations. If the application of steam to the purposes of war be likely to increase the sum of human calamity, so will the sum of human happiness be augmented by the impulse it will communicate to the whole social system.

The different modes of propelling vessels on the seas, forms a striking and peculiar picture in the eventful history of man. At first, content from circumstances with the simple application of the lever in the shape of an ore, we find at length the rowers greatly multiplied in number, and their oars augmented to enormous lengths, to give to the vessel as great velocity as possible. With the invention of cannon, and the ability of performing more extended voyages, came also the necessity of increasing the dimensions of ships. The additional altitude thus communicated, prevented the advantageous use of oars; and the great uncertainty of the wind made it desirable to supply its place when its force was insufficient, or when its directive energy operated contrary to that desired, by some other mechanical agent. Hence, by some it was imagined, that the force of the crew might be advantageously employed by other means than oars; and the communication of motion by means of paddle wheels was one of the earliest of these attempts. By some, also, condensed air was proposed as an agent, and by others the explosive force of gunpowder. The fall of water too was proposed; but all have vanished before the triumphant use of steam.

Among numerous attempts, however, the prize of the Academy of Sciences of Paris in 1753, for the best memoir on the subject, "*Sur la maniere de suppléer à l'action du vent sur les grands vaisseaux*," deserves to be particularly noticed, on account of its exhibiting the remarkable fact, that Bernouilli seemed to have looked to the force of man as the origin of propelling power: so little conception had that very illustrious philosopher, of the splendid application of steam affording the motive power. Bernouilli, to whom the prize of the Academy was awarded, entered into many elaborate investigations respecting the velocity capable of being communicated to a ship by the force of the crew, and endeavoured to ascertain the mean strength of a man, which he assumed as equivalent to the power of lifting twenty pounds through three feet in a second for eight hours in a day. The whole of this force not being usually exerted by a man in the action of rowing, he determines the actual part at $\frac{446}{1000}$ of the whole force. Adopting then the plane of resistance at 150 square feet as given by Bouguer, and assuming that the power required to produce a given velocity, is as the cube of that element, while the resistance is as the square, (a supposition not however in accordance with the opinion of many engineers) he computed the following table:

* It gives us much pleasure to remark, that Admiral Chapman's great work on ships of war, including the folio volume of plates, containing draughts of ships from a first-rate to the smallest class, is about to be translated from the Swedish by Mr. Morgan, and enriched with notes by Messrs. Morgan and Bennett.

Table of the Velocities which may be attained in a First-Rate by the Force of Men.

1000	7.00	8.68	5.01	6.21

This table will show how limited and confined were the views of that celebrated man, and by what more splendid and magnificent means than he anticipated, motion has been communicated to a vessel. It is a remarkable fact, that in the course of his memoir, Bernouilli mentions his having read the description of a steam engine, but remarks, that he does not consider its force, however it may be improved as capable of ever being advantageously applied to the purposes of navigation.

England, however claims the honour of first applying steam to the purposes of navigation. In 1736, Mr. Jonathan Hulls took out a patent for a boat to be propelled by the aid of steam, and in 1737, published a pamphlet in London illustrative of his plan. Its title is "*A Description and draught of a new-invented Machine for carrying Vessels or Ships out of, or into any Harbour, Port or River, against Wind or Tides.*" This little publication is now become exceedingly rare; but a copy of it was lately presented to the library of the Royal Society of Edinburgh, by its distinguished president, Sir Walter Scott.† This important and original thought was, however, never carried into practical execution by Hulls, probably from the want of funds and sufficient encouragement.

It is not our province in this article to trace the many other attempts that were made to carry on and perfect this great invention, but we may remark that in 1802, Mr. Symington actually constructed a steam boat on the Forth and Clyde canal, and that it was only abandoned in consequence of some narrow-minded proprietors of the navigation, conceiving that the undulation of the water occasioned by the motion of the wheel would wash and injure the banks; and in consequence, the boat was with great reluctance laid up in a creek of the canal near Bainford draw-bridge, exposed for years to public view. It is a remarkable fact, however, in the history of this great invention, that Mr. Fulton, for whom the Americans have with some unfairness claimed the original invention of the steam boat, actually visited Mr. Symington in 1802 and having mentioned the interest he felt in this new application of steam, Mr. Symington caused the engine fire of his boat to be lighted up, *and carried Mr. Fulton in the steam boat, from Lock No. 16, where the boat lay, four miles west the canal, and returned to the place of starting, in one hour and twenty minutes*, to the astonishment of Mr. Fulton, and several other gentlemen who happened at the outset to come on board.

This simple and incontrovertible fact decides in the most unquestionable manner, that *the invention of the steam boat is due, both in theory and practice*, TO GREAT BRITAIN.

To Mr. Fulton, however, belongs the great honour of having been the first who endeavoured to investigate on principle, the difficulties of the subject; and it is remarkable, that he derived his data from the experiments of the society for the improvement of naval architecture, a brief allusion to whose most useful labours has been already made at the end of the part devoted to resistance. M. Marestier, in an able report on the steam navigation of America, drawn up by command of the French minister of marine, and published at Paris, in 1824, has described at some length his method of proceeding. It is in principle this: having determined the resistance of the vessel, he inferred that the paddles must experience the same resistance, and that the engine must exert a force at the centre of effort of the paddles, equal to the resistance of the paddles. Assuming then the velocities of the piston and paddles as known, and equivalent to V and v, and the forces on the same as equivalent to F and f, he formed the proportion $V : v :: f : F$; and by dividing the whole force on the piston, by the force exerted by the steam on any given portion of its surface, he obtained the surface of the piston itself, and thence its diameter.

Knowing then the whole resistance on the paddles, and supposing only one paddle on each side to act at the same instant, the area corresponding to that resistance becomes known, the half of which determines the surface of one paddle. Knowing also from the number of strokes made by the piston, the number of revolutions made by the paddle wheels, the diameter of the wheel may be determined so as to ensure to the

* The English foot is equivalent to .9383 French feet.

† An account of this rare pamphlet, with a plate illustrating the steam boat of Jonathan Hulls, may be seen in the Edinburgh Philosophical Journal, vol. ix. It consists of forty-eight pages in duodecimo: was printed for the author, and sold, price sixpence, at the pamphlet shops in London and Westminster.

paddle the velocity originally assumed. Fulton having in this manner determined the force necessary to propel his boat, and accurately considered the mode by which it might be most successfully applied, avoided the great error of his predecessors, viz. attempting too much with an inadequate power, and gave to steam navigation that splendid and triumphant character which it now possesses; so that within little more than the half of a century after so transcendent a philosopher as Bernouilli had declared the utter improbability of its success, and within less than twenty years after its first successful attempt, has steam navigation arrived at such a perfection, that even a voyage to India has been accomplished, and a passage across the Atlantic, by no means regarded as an uncommon thing. What other achievements it is destined to perform, time must develop.

The form of a steam boat must in some degree assimilate to that of a sailing vessel, but there are many peculiar circumstances to be taken into account in considering of their construction: such as the particular kind of navigation for which they are destined—whether for the open sea, or for the shallower waters of rivers and lakes. If for the former an increased draught of water becomes necessary; but for the latter this element must be less considerable.* These considerations are to be inferred from the experiments on the resistance of fluids, in which it has been proved, that the quantity of water beneath the body in motion, has a very important influence on the resistance it experiences; and also, that if the water be at all confined the resistance is very considerably increased. This circumstance indeed is one of common observation among watermen; and it has been moreover observed in steam boats of different sizes on the same river, that as long as the water continued shallow, the smaller boat has had the advantage; but as the water has gradually deepened, the velocity of the larger boat has increased. A similar observation applies to the area of the midship section, which it is necessary to have as small as possible in boats destined for canals or narrow rivers, since the resistance depends on the relation of the area of the section of the boat, to the area of the section of the fluid.

Steam boats have a very considerable rolling motion, owing to the small proportion their breadth bears to their length, and to the height of the common centre of gravity of the principal weights. This motion arises from a deficiency in stability, and it would be advantageous therefore to adopt that form for the body most conducive to that very desirable quality. It is also of importance to have the greatest displacement with the least direct resistance, that is, with the least area of the midship section. Supposing the area of the midship section and the breadth to be given, the condition here alluded to, is in favour of a form, full near the load water line, and lean below. In such a body also, the centre of gravity of the displacement is high, which is favourable to the stability. It moreover enables the body forward and aft to be made finer than could be the case with a flat-floored midship section. The rising of the floor must, however, be limited by the consideration, that if the engines and other material weights are raised by it, the advantages might be counterbalanced by the effect this would have in raising the centre of gravity of the vessel. There is one great advantage in the extra draught of water, resulting from the rising floor, viz. that the keel, which, by its direct opposition to the water must tend very much to diminish the rolling motion, is at a greater distance from the axis of rotation, and consequently has a proportionally greater effect. The rising floor is now generally adopted in the English steam boats.

We have already remarked in a former part of this article, that the form of the sides between wind and water has a very material effect on the rolling of the vessel, and the observation equally applies to steam boats. For this purpose, the moment of stability should increase rapidly but uniformly, and as the vessel performs its alternate oscillations, the centre of gravity of the displacement should remain in the same transverse section. The form of the body also above and below the plane of flotation, should so accord with the position of the centre of gravity, as to cause the different oscillations of the vessel to be performed with the axis of rotation in the same constant plane. The elevation of the chimney, moreover, should be diminished as much as other circumstances will allow, in order that its weight, by raising the centre of gravity of the vessel, does not diminish in too great a degree the stability. The momentum also that the chimney acquires by its almost incessant vibrations, not only increases the rolling of the vessel, but creates also the chance of its being carried away, if the stability be not very well graduated. Not only indeed for the comfort of the passengers, and the perfect ease and security of the engines, but also for the general advantage of the vessel, ought the motions and strains of a steam boat to be rendered as moderate and uniform as possible.

In the English steam boats, the engines are so adapted as to have the axis of the paddle wheel generally *below* the surface of the deck. In the American steamers on the contrary, it is as generally *above*, and even some of their boats which are destined for merchandise have, according to M. Marestier, their engines on the deck. The sides of those vessels being, however, in general nearly vertical for some distance both above and below the water section, it would be advantageous with regard to easiness of motion, to endeavour to adjust the different weights so that the centre of gravity of the boat should be as nearly as possible in the plane of the deck.

In the earlier steam boats it was usual to give great comparative length, in imitation it is said of the relative proportion of row gallies. Thus in the following table, it will be remarked, that the length of the Clermont is to its breadth as 9.3 to 1; whereas the Connecticut, which had precisely the same length, had its breadth so increased as to present the relation of 4.2 to 1. The Clermont was constructed in 1807, and the Connecticut at a much later period. But the Enterprize presents an alteration in this particular of a still more striking kind, her length being 24.38 metres and her breadth 8.84, the two elements presenting the ratio of 2.8 to 1. The objects and destinations of these boats are without doubt very different; but it will be apparent, that in a mechanical structure like

* It is remarkable that until the year 1813, all the American steam boats were constructed with flat bottoms, and the Fulton was the first which had any rising in the floors.

a steam boat, wherein the weights are so very unequally distributed, the length ought not to exceed the breadth in any thing like the ratio first mentioned. In steam boats intended for river navigation, the length may without much impropriety be increased, because the strains are much less considerable than in the open sea. In the construction of steamers for rivers, some attention should be paid to length on account of the space necessary for turning them—a circumstance which may sometimes be productive of inconvenience.

The report of M. Marestier is replete with numerous and important tables, one of which we introduce, for the purpose of illustrating the relative dimensions of the length and breadth. The vessels are arranged according to the numerical relations of these dimensions, and not as M. Marestier has given them, according to the places at which they were built.

The Savannah	30 48	7.92	0·260	4.27
The Enterprize	24·38	8.84	0·363	

The column devoted to the relation of the length to the breadth, was found by dividing the latter dimension by the former. The average length of these boats is 39.82 metres, or 130.64 English feet, and their average breadth 7.15 metres, or 23.46 English feet. The draughts of water, it will be observed, are very variable, arising necessarily from the particular purposes for which the vessels are destined. The Savannah is the steamer that first crossed the Atlantic, and her draught of water, it will be perceived, is the greatest of the whole series. The Robert Fulton, which navigates the magnificent waters of the Mississippi, has a draught of 3.05 metres; whereas the Vesuvius, built for the purpose of navigating the same mighty stream, has only a draught of 1.8 metre, her breadth, however, being 1.53 metre less than the same dimension of the Robert Fulton, but her length two-thirds of a metre more.

With respect to the draught of steam vessels, there is, however, no necessity for its being so considerable as in sailing vessels, because their great length and straight of breadth will, in the event of their using sails, supply the place of depth, any useless degree of which serves only to increase the resistance; neither can there be any advantage in a difference of draught of water forward and aft in boats constructed with a rising floor; but, probably with flat floors, it may be requisite to assist the action of the water on the rudder.

Mr. Augustin Creuze has lately deduced from M. Marestier's drawings of the steam boat, the Chancellor Livingston, and also from several English boats, and from two which have been lately constructed in England for the service of the Norwegian Government, by Lieut. A. G. Carlsund, of the Swedish Royal Naval Engineers, the exponents of their different elements, as recorded in the following table, according to the parabolical method of Chapman, before alluded to.

	Length of the construction water line	Depth to the tangent of the midship section.	Exponent of the line of sections.	Exponent of the midship section.	Exponent of the water line.	Exponent of the displacement.

	95 75	6.25	2.4	4.54	6.54	2.13
American	150 47	5.41	2 12	4 72	4.03	2.27

It is of importance that the displacement and also the position of the centre of gravity should be accurately determined, on account of the great and constant weights on board a steam vessel being so considerable. It is usual to distribute the coals as much about the centre as possible, and to adjust the position of the centre of gravity of the engine, to the intended purposes of the vessel. It would be proper also to form an estimate of the stability of a steamer with regard to its length, by calculating what effect the removal of a weight to a certain distance either before or aft the centre of gravity, will produce a given difference in the draught of water. This weight being known might be employed as a scale by which to regulate the disposition of other weights; and it is from a neglect of this important particular, that steam boats float at a different draught of water from what was intended.

Unless the displacement is correctly determined, and the area of the midship section also known, and limited moreover to a constant quantity, the power of the engine cannot be determined, so as to ensure a given velocity. Another necessary cause for accuracy with regard to the displacement is, that any alteration from the water line, in relation to which the height of the axis of the paddle-wheels was determined, might

* The metre is equivalent to 39.37079 English inches.

materially affect the action of the paddles themselves; the height of the axis being adjusted in such a manner, that the wheels having a specific diameter, the paddles may obtain such an immersion in the water, as shall cause their inner edge to have a velocity at least equal to that of the vessel, to ensure the absence of resistance on the fore side of the paddle. Hence it appears, that the depth of the paddle depends on the proportion of the velocity of the vessel to that of the velocity of the outer edge of the paddle wheel. It is, moreover, found in practice, that the paddles will not work well if immersed in the water more than eighteen inches or two feet. This circumstance arises from the great loss of power occasioned by the obliquity of the stroke on their entrance into the fluid, and also on their leaving it, and the great quantity of water, moreover, they will lift.

The breadth of the paddle must be regulated by local circumstances, attending to the condition, that the greater the arc of the paddle, the less is the loss of power occasioned by the motion it communicates to the fluid. Bernouilli estimates this loss for the common oar to be $\frac{297}{1000}$ of the whole force applied. Sea-going boats should in general have their paddles narrower than boats intended for smooth water.

The number of paddles on a wheel is at present wholly determined by practice. One paddle for every foot the wheel is in diameter, is the general rule followed. If they are too near each other, they do not meet the water with all the advantage they ought; and if too far apart, the motion which their successive and distinct impact with the water communicates to the vessel is unpleasant.

Neither theory nor practice has yet determined where the axis of the paddle wheel should be placed with regard to the length of the vessel. M. Marestier has given us the following of its situation in several American boats. Its position is, however, always very much limited by that of the engine.

Positions of the Paddle Axis.

The Fulton - -	10.12	10.42	1 : 1.03

This table proves that the position of the paddle axis is very variable in different vessels. In the Chancellor Livingston it is placed in the middle of its principal axis, and very nearly so in the Fulton: but in the Philadelphia of Baltimore, the deviation from the centre is very considerable, and the greatest of the whole series. In the United States, the Virginia and the Washington, the deviation also is very great. Much remains yet to be done to perfect this important part of the subject.

Many of the boats on the Mississippi have their wheels abaft, that they may be protected from the logs of timber incessantly floating on that mighty river, thus practically exemplifying the original idea of Hulls. Many vessels also, intended only for short passages, and where a small draught of water is necessary, are built with two bodies, with the wheel placed between them. This plan, however, is not found advantageous for boats with any considerable draught of water, because, in addition to their weakness, there is an increase of resistance resulting from the water passing with great velocity through a confined channel. Boats have been tried with two pair of paddle wheels, and the Dutch are now building a steam frigate with four engines, each of 100 horse power, to act on two pair of paddle wheels.

When there are two paddle wheels on each side, their relative velocities, with respect to the water, should be equal, in order that they may exert an equal force on the vessel. If this were not the case, the aftermost wheel would operate disadvantageously: for as the water on which the aftermost wheel acts, has had an increased velocity communicated to it by the action of the foremost wheel, the absolute velocity of the aftermost wheel must be proportionally greater than that of the foremost; a circumstance which would require a greater quantity of steam, and consequently a greater consumption of fuel. There would also be a waste of power, unless each pair of wheels had separate engines: and it is probable that the aftermost wheels would lose a portion of their effect, in consequence of the disturbed state of the water they acted on.

The following important table was communicated to M. Marestier by one of the principal engineers of New York, as the result of his experience with regard to the proportions between the dimensions of a vessel and its engine; and, in order to make this part of his useful and important work as complete as possible, he has added another table, the result of his own inquiries, containing the principal proportions of the engines and paddle wheels, &c. of the steam boats, the dimensions of which have been given in the preceding tables.

A Table of the principal Proportions of Steam Engines as adapted to Vessels of known dimensions.

M. Marestier has also given the following comparative table of the results he has observed, and calculated for ten boats, of which he was able correctly to ascertain the velocities.

In the first column, the measure of the *elasticity of the steam*, is represented by the height of the column of mercury it will support in a vacuum.

The column devoted to *the proportion of the paddles*, is the quotient of the rectangle of the breadth and draught of water of the boat, divided by the area of one of the paddles.

The number which he terms *the factor of the diameter of the wheels*, he obtained by considering, that if the vessels were similar, and the resistances to the paddles bore in all of them the same invariable relation to the resistance of the hull, the diameter of the paddle wheels would be equal to the velocity of the boat multiplied by a constant factor, and divided by the number of double oscillations of the piston. The mean of these factors being between 29 and 30, it follows, that if the proportion the velocity of a steam boat bears to the number of strokes of the piston, be multiplied by 29 or 30, the result will give nearly the dimensions of paddle wheels similarly proportioned to those in the American boats.

The last column denominated *the multiplier*, is a number which Marestier deduced, to show the relation which the true velocity of a boat bears to the following quantity: The square root of the product of the height of the column of mercury the steam will support, the stroke of the piston, and the square of its diameter, divided by the square root of the product of the rectangle of the breadth and draught of water of the vessel, and the diameter of the paddle wheel.

If the different boats were equally perfect in their respective elements, there would be no necessity for a different multiplier for each boat; but, as the forms of their bodies, and the qualities of their engines differ considerably, the multipliers must necessarily vary.

M. Marestier [illegible] that the variation for the first nine boats recorded in the table is between twenty and twenty-five. The Savannah he did not include in his computation, as he had no precise information respecting her.

Table of the comparative proportions [illegible] deduced from ten American Steam Boats.

We shall now endeavour to explain the principles by which M. Marestier deduces so ingeniously the terms *factor* and *multiplier*, the values of which are recorded in the two last columns of the preceding table.

To accomplish this he supposes *the motion of the vessel to become uniform, and the force of the steam constant*: and on this hypothesis, and the data he has collected in the preceding table, he investigates the proportions which exist between the power of the engine, the dimensions of the vessel, of the paddles and the wheel. He assumes, moreover, *that the resistance of the paddles is equal to the resistance of a surface moved in the fluid in a direction perpendicular to itself, and having a velocity equal to the mean velocity of the paddles.* This surface, which he denominates *the resisting surface of the paddles*, is represented by . . a^2

The velocity of the resisting surface by U

The resisting surface of the vessel by b^2

And the velocity of the vessel by . V

Each of these quantities he proposes to derive from experiment.

1. The resistance of the hull being supposed proportional to the square of the velocity, is equivalent to $k b^2 V^2$, the function k being the measure of the direct resistance corresponding to the unity of surface and velocity.

Then the velocity with which the paddles strike the fluid being $U - V$, the resistance they experience will be $k a^2 (U - V)^2$.

Hence it follows, that

$$k b^2 V^2 = k a^2 (U - V)^2,$$

* The nautical mile is equal to 1851.85 metres, or about 6077.58 English feet.

and $U = \left(1 + \frac{b}{a}\right) V.$

The velocity of the vessel is therefore always proportional to that of the paddles, while the resisting surface of the vessel bears a constant relation to the surface of the paddles.

2. The moments arising from the action of the paddles on the water, and the steam on the piston, are equivalent to each other, omitting the effects of friction. The absolute velocity of the paddles being also U, and the resistance they meet with $k\,a^2\,(U-V)^2$ the moment of their action, will be

$$k\,a^2\,(U-V)^2\,U.$$

Supposing q to represent the density of the mercury, h the altitude of the column the steam will support, P the surface of the piston, and v the measure of its mean velocity: then will the moment of the piston be equivalent to $q\,h\,P\,v$,

and consequently $q\,h\,P\,v = k\,a^2\,(U-V)^2\,U.$

3. Since the effect of the friction of the machine is to diminish the effect of the moving force communicated from the piston to the paddles, a portion only of the moving force $q\,h\,P$ is taken, and which is represented by $m\,q\,h\,P$. Hence we obtain the equation

$$m\,q\,h\,P\,v = k\,a^2\,(U-V)^2\,U.$$

and since $U = \left(1 + \frac{b}{a}\right) V,$

we obtain by the necessary reductions,

$$V = \sqrt[3]{\left(\frac{m\,q\,h\,P\,v}{k\,b^2\left(+\frac{b}{a}\right)}\right)}, \text{ and}$$

$$U = \sqrt[3]{\left(\frac{m\,q\,h\,P\,v}{k\,b^2}\left(1+\frac{b}{a}\right)^2\right.}$$

4. From these formulæ we may draw the following conclusion:—that *the cube of the velocity of the vessel is less than the power of the engine, divided by the resistance of the vessel;* and that *the cube of the mean velocity of the paddles is also greater than the same quantity*—a limit only to be attained when the paddles are infinite.

5. If we suppose a second boat to exist, the elements U′, V′ a′, b′, &c. of which are analogous to those of U, V, a, b, &c. adopted for the former boat, we may obtain by the common processes of reduction

$$\frac{V'}{V} = \sqrt[3]{\left(\frac{m'\,h'\,P'\,v'}{m\,h\,P\,v}\cdot\frac{b^2}{b'^2}\cdot\frac{1+\frac{b}{a}}{1+\frac{b'}{a'}}\right)},$$

$$\text{and } \frac{U'}{U} = \sqrt[3]{\left(\frac{m'\,h'\,P'\,v'}{m\,h\,P\,v}\cdot\frac{b^2}{b'^2}\cdot\left(\frac{1+\frac{b'}{a'}}{1+\frac{b}{a}}\right)^2\right)}.$$

So also when the resisting surfaces of the paddles are, in both vessels, proportional to the resisting surfaces of their hulls,

we obtain $\frac{b'}{a'} = \frac{b}{a};$

and consequently $\frac{V'}{V} = \frac{U'}{U} = \sqrt[3]{\left(\frac{m'\,h'\,P'\,v'}{m\,h\,P\,v}\cdot\frac{b^2}{b'^2}\right)}.$

Hence it follows, that *the velocities of the boats are proportional to the velocities of the paddles, and they are also in a direct proportion to the cube root of the power of the engines, and in an inverse proportion to the cube root of the resistance of the vessels.* M. Marestier considers this proposition nearly general; because, unless there is a very great disproportion in the dimension of the vessels, the relation of $1+\frac{b}{a}$ to $1+\frac{b'}{a'}$, cannot differ much from unity.

Throughout these investigations, M. Marestier has regarded h as the altitude of the column of mercury, which the steam when acting on the piston will support, and determined the effort of the piston, under the supposition that the vacuum on the contrary side of the piston is perfect; but as such a condition cannot exist, the quantity h should be diminished by the height which the steam remaining on the contrary side of the piston, will depress the mercury from the altitude at which it would stand in a common barometer. This is an important consideration when comparing one boat with another, because the degree of the vacuum must depend wholly on the goodness of the engine.

6. From the equations $b\,V = a\,(U - V)$,

and $m\,q\,h\,P\,v = k\,a^2\,(U-V)^2\,U$,

we may deduce $U V^2 = \frac{m\,q\,h\,P\,v}{k\,b^2}.$

Therefore whatever may be the dimensions of the paddles, the product of their velocity and the square of the velocity of the vessel is in proportion to the power of the engine.

Although the power of the engine has been considered as known, it is seldom that the velocity of the piston can be taken arbitrarily. The relation of this velocity to that of the paddles is almost always invariable, and therefore the velocity of the piston alters with any increase or diminution in the size of the paddles. This however will not make any change in the conditions of the preceding question; but the value of v will vary according to the alteration. It may happen either that the velocity of the piston is too great to admit of an adequate supply of steam, or that the supply of vapour is too great, and some necessarily escapes by the safety valve. In the first case, the elastic force of the vapour will diminish until the movement of the piston shall correspond to the quantity of steam supplied; and in the second case to prevent the loss of steam, the intensity of the fire must be diminished; but then the power of the engine will be reduced in the proportion of the actual velocity of the piston to that which it ought to have.

That the velocity of the piston may correspond to the quantity of steam furnished by the boilers, the mechanism must be so arranged as to satisfy the equation

$$U = \sqrt[3]{\left(\frac{m\,q\,h\,P\,v}{k\,b^2}\left(1+\frac{b}{a}\right)^2\right)};$$

or if r represents the relation between the velocities of the piston and paddles, we may obtain the equation

$$r = \frac{U}{v} = \sqrt[3]{\left(\frac{m\,q\,h\,P}{k\,b^2\,v^2}\left(1+\frac{b}{a}\right)^2\right)},$$

Of the quantities a, b, h, P, r, U, V, and v contained in the equations.

$$U = \left(1 + \frac{b}{a}\right) V,$$

$$m\,q\,h\,\mathrm{P}\,v = k\,a^2\,(\mathrm{U}-\mathrm{V})^2\,\mathrm{U},$$
and $\mathrm{U} = r\,v$,

any five being known, the remaining three may be readily determined. Thus, if the values of the elements a, b, h, P, r, are known, and it be required to determine the values of U, V, and v, we shall obtain from the preceding equations

$$\mathrm{U} = \left(\frac{1}{b}+\frac{1}{a}\right)\sqrt{\frac{m\,q\,h\,\mathrm{P}}{k\,r}},$$

$$\mathrm{V} = \frac{1}{b}\sqrt{\frac{m\,q\,h\,\mathrm{P}}{k\,r}},$$

$$\text{and } v = \left(\frac{1}{b}+\frac{1}{a}\right)\sqrt{\frac{m\,q\,h\,\mathrm{P}}{k\,r^3}}.$$

Since the velocity of the vessel is independent of the element a, it follows, that as long as the value of r remains unchanged, the surface of the paddles may be either increased or diminished without producing any alteration in the velocity of the boat. At the same time also it appears, from an inspection of the function representing the value of v, that we cannot augment the dimensions of the paddles, without diminishing the velocity of the piston, and causing a greater consumption of steam and fuel.

If the diameter of the wheels be diminished, the velocity of the steam boat will be increased; but the velocity of the piston and the power of the machine being increased also, will require a greater consumption of steam and fuel. Hence an increase of velocity may be obtained by diminishing the diameter of the wheels, provided that the boiler will furnish more steam than the engine consumes.

If, on the contrary, the diameter of the wheels be increased, the vessel will lose velocity: but this cannot be avoided, if after having increased the surface of the paddles as much as is consistent with other circumstances, it is found that the engine has too great a velocity for the supply of steam furnished by the boiler.

If, again, the diameter of the wheels be diminished by taking away a portion of each paddle, the velocity of the vessel will be increased, because the value of the element r is diminished: but then it must be remarked, that more steam will be consumed than if the change had been made in the diameter, without diminishing the surface of the paddles.

When any alteration is made in the mechanism which communicates motion from the piston to the wheels, the elements r, U, V, and v, become respectively r', U′, V′, and v'. Hence we have

$$\mathrm{V}' = \frac{1}{b}\sqrt{\frac{m\,q\,h\,\mathrm{P}}{k\,r'}},$$

$$\text{and } v' = \left(\frac{1}{b}+\frac{1}{a}\right)\sqrt{\frac{m\,q\,h\,\mathrm{P}}{k\,r'^3}};$$

$$\text{Consequently, } \mathrm{V}' = \mathrm{V}\sqrt{\frac{r}{r'}} = \mathrm{V}\sqrt[3]{\frac{v'}{v}},$$

$$v' = v\sqrt{\frac{r^3}{r'^3}},$$

$$\text{and } r' = r\sqrt[3]{\frac{v^2}{v'^2}}.$$

Hence it follows, that when the piston does not partake of the velocity which the steam furnished by the boiler would admit in any change of the mechanism, the velocity of the boat will be reduced in proportion to the cube root of the velocity of the piston: and in order that the vessel may acquire the velocity which the engine is capable of imparting, the value of r must be diminished inversely as the cube root of the square of the velocity of the piston.

The value of $\mathrm{V} = \frac{1}{b}\sqrt{\frac{m\,q\,h\,\mathrm{P}}{k\,r}}$ being more simple than that before deduced for the same element, admits of an easier comparison with the velocities before observed. It admits, however, of further simplification.

For this purpose let p represent the diameter of the piston, and π the relation of the diameter to its circumference, then will

$$\mathrm{P} = \frac{p^2\pi}{4}.$$

In the American vessels, the wheels generally make one turn for every double stroke of the piston; and, therefore, supposing c to represent the length of a stroke of the piston, and n the number of revolutions of the wheel in a minute, we shall have

$$v = \frac{2n\,c}{60} = \frac{nc}{30}.$$

Calling also the absolute diameter of the paddle wheels D, its mean diameter will be δ D, where δ denotes a quantity to be determined by experiment. Hence we have

$$\mathrm{U} = \frac{n\times\pi\,\delta\,\mathrm{D}}{60},$$

$$\text{and consequently, } r = \frac{\mathrm{U}}{v} = \frac{\pi\,\delta\,\mathrm{D}}{2\,c}.$$

The resisting surface of the vessel before assumed as equivalent to b^2, depends essentially on the shape of the vessel, and perhaps on its velocity; but as it is known that it increases in proportion as the draught of water and breadth are augmented, we may suppose it proportional to the rectangle B of the dimensions alluded to, and which therefore furnishes the equation

$$b^2 = \beta\,\mathrm{B},$$

the element β being determined by experiment.

Substituting this value of b^2 in the equation

$$\mathrm{V} = \frac{1}{b}\sqrt{\frac{m\,q\,h\,\mathrm{P}}{k\,r}},$$

$$\text{and we shall have } \mathrm{V} = \sqrt{\frac{m\,q}{2k\,\beta\,\delta}}\sqrt{\frac{h\,c\,p^2}{\mathrm{B\,D}}}.$$

The density of the mercury $q = 13.6$; and it may also be remarked that the value of k, when the body exposed to the impulse of the water is thin, as in the case of the paddles, is about $\frac{6}{100}$, unity being the weight of a cubic metre. There are several causes, however, which render it difficult to determine the values of m, β, and δ, as they vary under different circumstances. The best boats, M. Marestier observes, will be found to be those where the value of $\frac{m}{\delta\beta}$ is the greatest.

8. For the object in view, it is sufficient to know the value of $\sqrt{\frac{m\,q}{2\,k\,\beta\,\delta}}$, which has been designated the

multiplier. Supposing it to be represented by M, we have

$$V = M \sqrt[3]{\frac{h\,c\,p^2}{B\,D}}.$$

In the last table it will be perceived that M. Marestier has deduced the multipliers for several vessels, the values of which, omitting the instance of the Savannah, vary from about 20 to 25, and the mean he fixes at 22. Since, however, the value of the multiplier, all other things remaining the same, depends on the perfection of the engine and vessel, it cannot be strictly correct to apply to one vessel a number deduced by experiments on others far inferior to it. It is to be remarked that the velocities which M. Marestier has given of the American boats are small in comparison to those of the more modern English boats. The latter boats require therefore higher multipliers than the former.

9. The equation $U = \left(1 + \frac{b}{a}\right) V$ before given, will undergo some convenient modifications, by substituting in it the values of b and U deduced from the equations $b^2 = \varepsilon B$, and $U = \frac{n\,\pi\,\delta\,D}{60}$, and also adopting for a^2 the resisting surface of the paddles, the quantity $A\nu$, the function A representing the area of one of them. These substitutions will transform the first-mentioned equation $U = \left(1 + \frac{b}{a}\right) V$, into

$$\frac{n\,\pi\,\delta\,D}{60} = \left(1 + \sqrt{\frac{\varepsilon}{\nu}} \sqrt{\frac{B}{A}}\right) V,$$

and from which we may deduce

$$D = \frac{60\left(1 + \sqrt{\frac{\varepsilon}{\nu}}\sqrt{\frac{B}{A}}\right)}{\pi\,\delta} \cdot \frac{V}{n}.$$

The function $\frac{60}{\pi\,\delta}\left(1 + \sqrt{\frac{\varepsilon}{\nu}}\sqrt{\frac{B}{A}}\right)$ is that which has been denominated *the factor of the diameter of the wheels*, and of which the mean value is thirty. If we designate this function by F, we shall obtain the equation

$$D = F.\frac{V}{n}.$$

10. By means of the equations

$$V = M\sqrt[3]{\frac{h\,c\,p^2}{BD}}, \text{ and } D = F.\frac{V}{n},$$

in which the co-efficients M and F, taken at their mean experimental values are 22 and 30, we can resolve such questions as relate to the proportions and principal dimensions of engines and vessels constructed on principles similar to those of the Americans. We obtain, for example, from the equations referred to

$$n = M\,F\sqrt[3]{\frac{h\,c\,p^2}{B\,D}},$$

which enables us to remark, that though from the first of the two equations given, it appears to be advantageous to diminish the diameter of the wheels, that cannot be done unless the boiler will produce enough of steam to admit of their performing a greater number of revolutions.

Again, by eliminating D from the same equations, we obtain,

$$V = \sqrt[3]{\left(\frac{M^2}{F} \cdot \frac{n\,h\,c\,p^2}{B}\right)};$$

or since,

$$\sqrt[3]{\frac{M^2}{F}} = 2.53 \text{ nearly},$$

we may have,

$$V = 2.53\sqrt[3]{\frac{n\,h\,c\,p^2}{B}}$$

Hence it appears that the velocity of a steam boat is equal to the cube root of the product of the following quantities: *The altitude of the column of Mercury the steam will support, the square of the diameter of the piston, the length of its stroke, and the number of times it is raised in a minute*; divided by *the cube root of the product of the breadth of the vessel into its draught of* water, and the quotient multiplied by *a constant co-efficient*.

By employing this expression for calculating the velocities of the first nine vessels contained in the comparative table it will be found, says M. Marestier, that the error is generally less than one-tenth of the actual value.

The coefficient 2.53 above deduced, depends on the form of the vessel. Its value might be 2.25 for a form experiencing apparently a great resistance; or it may be 2.75, or even more, for a contrary form.

11. If the value of B be regarded as unknown, we shall obtain,

$$B = \frac{M^2}{F} \cdot \frac{n\,h\,c\,p^2}{V^3};$$

or since the value of the co-efficient $\frac{M^2}{F}$ is nearly equivalent to 16, we shall have, $B = \frac{16\,n\,h\,c\,p^2}{V^3}$.

Hence, the engine being given, we can determine the area of a parallelogram, whose base shall be the breadth of a vessel which the engine can move with a given velocity, and altitude equal to the draught of water.

12. From the equation $n\,c\,h\,p^2 = \frac{BV^3}{16}$ we may also find the power it is requisite an engine should possess, to enable it to move a given vessel with a determinate velocity. We see, moreover, that this force increases as the cube of the velocity.

13. Having found that

$$v = \frac{c\,n}{30}, \text{ or } c\,n = 30\,v,$$

we shall obtain, by substituting in the value of V before given, that $V = \sqrt[3]{\left(\frac{M^2}{F} \cdot \frac{30\,v\,h\,p^2}{B}\right)}$;

and when the velocity of v is equivalent to $\frac{8}{10}$ of a metre, which is the case in most of the American boats, we shall farther have $V = 7.3\sqrt[3]{\frac{h\,p^2}{B}}$.

This equation may be employed in the same manner as the preceding, to determine the size of a vessel, or the power of an engine, by supposing B or $h\,p^2$ as unknown.

M. Marestier objects to the method commonly employed of estimating the power of a steam engine, by the number of horses it would require to perform the same quantity of work, since the nominal power of the engine under these circumstances, must very much depend on the estimated power of a horse. He proposes a method, certainly of a much more philosophic character, and capable of affording more accurate results. *Multiply*, says he, *the height of the column of mercury the steam will support, by the square of the diameter of the cylinder, and the mean velocity of the piston; sixty-six and two-thirds of this product will be the number representing the horse power. Then will the velocity be equal to twice the cube root of the quotient of the number of horses, divided by the rectangle of the draught of water, and the breadth of the vessel.*

The power of an engine capable of communicating a required velocity to a boat may be found, he informs us, by multiplying the cube of the velocity by the breadth, and by the draught of water, and dividing the resulting product by 7.26, or by 6, as the circumstances of the vessel may require.

The surface of the parallelogram also, which has the breadth of the vessel for its base, and the draught of water for its altitude, may be determined, by dividing the number of horse power of the engine, by the cube of the required velocity, and multiplying the resulting quotient by 7.26, or 6, as the conditions of the vessel may require.

In considering the motions of steam vessels in rivers, M. Marestier introduces the consideration of the velocity of the current, and also attends to the effect produced, by causing the action of the engine to be applied to winding a rope round a roller, the outer end of the rope being attached to a fixed point on the shore. His general results are as follow: *To stem a current with the least consumption of fuel, the absolute velocity of the vessel should be only half the velocity of the steam. That the velocity resulting from the use of the rope and roller is greater than that which results from the use of the paddle-wheel, in the proportion of the cube root of the velocity of the paddle to the cube root of the velocity communicated by the paddles to the vessel. That to enable the vessel to stem a current with an absolute velocity equal to half the velocity of the current, it requires three times the motive power, if that power acts on board the vessel, that would be necessary if the power were applied to the rope. That when the current is rapid, it is advantageous to use the rope for hauling, in order to stem it; but that if the current is not strong, it is preferable to use the paddles; and that the paddles should always be used in descending a stream, when the absolute velocity of the vessel is greater than the velocity of the paddles, or when the velocity of the stream is greater than the velocity with which the paddles strike the water, which will generally be the case.**

Much remains to be done to perfect the theory and practice of steam boats: yet in a department of knowledge so comparatively new, it is remarkable what rapid steps have been already made towards its improvement. "*The motion of boats, their forms*, and *proportions*," says Mr. Tredgold, in an ingenious and able paper on the subject,† "will afford many fine subjects for the application of science." Let us hope, that "Man, nature's minister and interpreter," will not cease his endeavours to carry it onwards to perfection.

Mr. Tredgold, in his ingenious disquisition, observes, that in still water, it may be assumed, that the resistance of the same vessel is sensibly proportional to the square of the velocity: the variation from the law being, he considers, too small to produce a sensible effect within the range to which the velocity is limited in practice. Therefore if a be the force that will keep the boat in uniform motion at the velocity u, the force that will keep it in motion at the velocity, will be found by the analogy,

$$u^2 : v^2 : : a : \frac{a\,v^2}{u^2},$$

which is the measure of the resistance with the velocity v. Hence the mechanical power required to keep the boat in motion with the same velocity, will be $\frac{a\,v^3}{u^2}$; and from which it follows, that the power of a steam engine to impel a boat in still water, must be as the cube of its velocity. Therefore, if an engine of twelve horses power will impel a boat at the rate of seven miles an hour in still water, and it be required to determine what power will move the same boat at ten miles per hour, we shall have

$$7^3 : 10^3 : : 12 : \frac{10^3 \times 12}{7^3} = 35;$$

or an engine of thirty-five horses power.

This immense increase of power to obtain so small an increase of velocity, says Mr. Tredgold, ought to have its influence in fixing upon the speed of a boat for a long voyage, and its proportion ought to be adapted for that speed, with a proper excess of power for emergencies. A low velocity should be chosen, when goods as well as passengers are to be conveyed. The example before given, places this in a very striking point of view: for to increase the velocity of the same boat from seven to ten miles an hour, requires very nearly three times the power, and of course three times the quantity of fuel, and three times the space for stowing it, besides the additional space occupied by a larger engine. Therefore if seven miles per hour will answer the purposes of the trade the vessel is to conduct, the advantages of the lesser speed must be evident.

According to these principles, Mr. Tredgold has computed the following table, illustrating the power necessary to communicate to a boat different velocities

2 miles per hour	5½ horses power.
4 - - -	13
5 - - -	25
6 - - -	43
7 - - -	69
8 - - -	102

* The work of M. Marestier is the most important that has yet appeared on the subject of steam navigation, and we earnestly recommend its elaborate content to the attention of our readers. The report to the Institute on it was made by Sane, Biot, Poisson, and Dupin. These distinguished men remark, "Lorsqu'un nouveau genre de forces mécaniques s'introduit d'une maniere utile dans quelque branche de l'industrie humaine, il donne au peuple qui s'en empare le premier, ou que l'exploite sur la plus grande échelle, un puissant moyen de superiorité sur les autres peuples. Souvent, enfin, le renversement des rapports de prosperité, de richesse et de puissance entre les nations, est la suite necessaire de l'adoption et du progrès des appliations d'une espece nouvelle de forces mécaniques."

† See an Essay on Steam Boats by Mr. Tredgold, in Mr. Partington's Historical and Descriptive Account of the Steam Engine.

In short voyages, the extra quantity of engine room and tonnage for fuel is not so objectionable; but in a long voyage, it reduces the useful tonnage to so small a proportion, as to render it doubtful whether such vessels will answer or not. The consumption of fuel to produce a given effect, is much greater than in engines on land; and perhaps much in consequence of the draught of the chimney, and the limited space for the boiler.

When the paddles of a steam boat are in action, there is a point in each paddle, wherein if the whole reaction of the fluid was concentrated, the effect would not be altered. This point Mr. Tredgold denominates the centre of reaction.

By supposing the fluid at rest, the velocity of the centre of reaction V, and the velocity of the boat v, the velocity with which the paddles strike the water will be $V - v$. Or the difference between the velocity of the paddles and the velocity of the boat, is equal to the velocity with which the paddles act on the water. Hence when these velocities are the same, the paddles have no force to impel the boat; and if the paddles were to move at a slower rate, they would retard it.

Now, as $V - v$ represents the velocity, the force of the reaction will be as $(V - v)^2$, since this quantity is proportional to the pressure producing the velocity $V - v$. But during the action of the paddles, the water yields with a velocity $V - v$; and since the velocity of the boat is v, the effective power is as

$$V - v : v : : (V - v)^2 : v\,(V - v).$$

The effect of this power in a given time, is a maximum, when $v^2\,(V - v)$ is a maximum; that is when $2\,V = 3\,v$; or when the velocity of the centre of reaction of the paddles is $1\frac{1}{2}$ time the velocity of the boat.

It is desirable that the action of the paddles should be as equable and continuous as possible, unless they be arranged so that the variation of the power of the engine may coincide with the variation in the action of the paddles. But in attempting to render the action of the paddles equable, their number ought not to be increased more than can be avoided, because there is not then time for the water to flow between them, so as to afford a proper quantity of reaction; neither do they clear themselves so well in quitting the water. If we suppose WL, Fig. 3. Plate DI. to be the line the water would assume when at rest, the most favourable arrangement, with the smallest number of paddles, appears to be, to make the paddle A of the wheel A just entering, when the preceding one B is in a vertical position, and the one C quitting the water. This arrangement allows time for the water to flow between, and for it to escape from the retiring paddles. If a smaller number be employed, there will be a short interval, during which none of the paddles will be in full action. The utmost variation will be between the positions of the wheels A and B, and an intermediate position is shown by the wheel C.

To determine the radius of the wheel, or the depth of the paddles, when the number of paddles is given, becomes an easy problem, when the preceding conditions are to be adhered to.

For this purpose, put AO, Fig. 4. $= r$, and the depth A a of the paddle $= x$. Let also n represent their number. Then $\frac{360^\circ}{n}$ will be measure of the angle AOB, contained between two adjacent paddles; and $r \cos. \frac{360^\circ}{n} = \mathrm{O}\,a$, will be the cosine of the same angle, being the interval from the centre of the wheel to the surface of the water.

$$\text{Hence,} \qquad r \cos. \frac{360^\circ}{n} = r - x;$$

or $r\left(1 - \cos. \frac{360^\circ}{n}\right) = x$, the depth of the paddles; and $\dfrac{x}{1 - \cos. \frac{360^\circ}{n}} = r = \mathrm{A}\,o$, is the radius of the wheel.

From these equations Mr. Tredgold derives the following rules for finding the radius of the wheel, when the number and depth of the paddles are given. *Divide 360 by the number of paddles, which will give the degrees in the angle contained between two adjacent paddles. From unity subtract the natural cosine of this angle, and the depth of the paddles divided by the remainder will give the radius of the wheel.*

Thus, if the number of paddles be 8, Fig. 5. and their depth $1\frac{1}{2}$ foot, we shall have $\frac{360^\circ}{8} = 45^\circ$, the cosine of which is .7071. Therefore $\frac{1.5}{1 - .7071} = 5.12$ feet, the radius of the wheel.

Again, if the number of paddles be 7, Fig. 4. and their depth 1.5 foot as before, we again have $\frac{360^\circ}{7} = 51^\circ\ 26'$, the cosine of which is ·6234. Consequently $\frac{1.5}{1 - .6534} = 4$ feet, the radius of the wheel desired.

Both these examples are illustrated in Fig. 6, and it may be remarked with respect to them, that, when the depth of the paddles is fixed, the greater number of paddles should have the preference, because the first impression on the water is then less vertical. The difference may be readily perceived, by comparing the angles at which the paddles A and a strike the water. It will also be remarked, that the larger wheel must have a less tendency to throw up the water behind at C.

It is obvious, continues Mr. Tredgold, that, by enlarging the wheel, the obliquity of the action on entering the water may be reduced; but it also may be done by lessening the depth of the paddles, as will be evident from Figs. 3 and 4, where the angles are the same in both wheels. Hence it is useful to be able to find the depth: and if the number of the paddles and the radius of the wheel be given, the depth may be found by the foregoing rule:

Multiply the radius of the wheel by the difference between unity and the natural cosine of the angle contained between two paddles, and the product is the depth required. Suppose, for example, the radius to be 4.5 feet, and the number of paddles eight, there will be 4.5 $(1 - .7071) = 1.318$ *feet, for the depth of the paddles.*

Mr. Tredgold thinks eight paddles to be as small a number as ought to be adopted, and where large wheels can be admitted, nine or ten might be used with advantage, but where many paddles are employed, the wheels must necessarily be of large diameter, to keep them narrow. The advantages of wheels of large diameter consist in the favourable direction they strike the water, and also quit it; the paddles are also more distant from one another, and while they have more re-action on the water, they splash it about much less; the weight of the wheel also renders it more effective as a regulator of the forces acting upon it. On the contrary, there are some strong practical objections to very large wheels for sea vessels; they give the force of the waves a greater hold on the machinery, they are cumbersome and unsightly, and they raise the point of action too high above the water line, so that the choice requires both experience and judgment.

The best position for the paddles appears to be in a plane passing through the axis, as represented in the figures. If they be in a plane which does not coincide with the axis, they must either strike more obliquely on the fluid in entering, or lift up a considerable quantity in quitting it. With respect to the shape of the paddle, it is clear that it should be such that the resistance to its motion should be the greatest possible, and the pressure behind it the least possible. These conditions appear to be fulfilled in a high degree by the simplest of all forms, the plane rectangle; but we might learn much from a judicious set of experiments on this subject.

As there is some variation in the force of re-action against the paddles, it may in some measure be compensated by making its periods coincide with the variation in the force of the engine. To effect this, the stroke of the engine should be made in the same time as is occupied by that part of the revolution of the paddle wheel, which is expressed by a fraction, having the number of paddles for its denominator, and the piston should be at the termination of its stroke, when one of the paddles is in a vertical position. For, when one of the paddles is in a vertical position, as in the wheel A, Fig. 2, the re-action is the least, and it is greatest when two paddles are equally immersed, as in the wheel B, at which time the force would be acting at right angles to the crank.

Having shown the power that is necessary to keep a boat in motion in still water, it will be some advantage to resume the inquiry in the case where it moves in a stream or current; and, for that purpose, let v be the velocity of the boat, and c that of the current; a being the resistance when the boat is in motion with the velocity u.

Then the resistance to be overcome to give the boat the velocity v, is, when the motion is *with the stream*,

$$u^2 : (v - c)^2 :: a : \frac{a(v-c)^2}{u^2}.$$

And, when the boat moves *against the stream*, we have

$$u^2 : (v + c)^2 :: a : \frac{a(v+c)^2}{u^2}.$$

Hence the power is expressed in either case by

$$\frac{a(v \mp c)^2}{u^2},$$

the *upper* sign of which is to be attended to when the motion is *with the current*, and the *lower sign when it is against it.*

When c, the velocity of the current, is nothing, the result is the same as before. But the resistance in still water is not the mean between the resistances in the direction of the current, and against the current; consequently, the mean rate of a boat, which alternately goes with and against a current, must be less than the mean rate in still water. The mean resistance is

$$\frac{a\,v\,(v^2 + c^2)}{u^2},$$

while the resistance in still water is only $\frac{a\,v^3}{u^2}$, the difference between which and the former is $\frac{a\,v\,c^2}{u^2}$; a quantity depending on the velocity of the current, and for any particular case, should be calculated from the mean motion of the current.

When a boat advances with a current, the velocity with which the paddles act on the water will be $V + c - v$; and when the boat moves against the current, it will be $V - c - v$; consequently, in either direction it is $V \pm c - v$; and the force of re-action $(V \pm c - v)^2$. But the effective resistance of the boat is as

$V \pm c - v : v :: (V \pm c - v)^2 : v\,(V \pm c - v)$; and its effect in a given time is a maximum, when $v^2\,(V + c - v)$ is a maximum, that is when $V = \frac{3\,v \mp 2\,c}{2}$, or when $V = 1.5\,v \mp c$. Moreover, $v = \frac{2\,(V \pm c)}{3}$.

When c vanishes, or the boat moves in still water. $\frac{2\,V}{3} = v$, the same as before. The mean also between moving against and with the current is $\frac{2\,V}{3} = v$. Therefore, where the velocity cannot be changed to suit the circumstances, this will be the best proportion for all cases. Where the force of a current is considerable, it would be extremely desirable to have the power of altering the velocity of the wheels; but this should not be accomplished by any alteration of velocity in the steam piston, since whatever change is made in its velocity must affect the power of the engine. There is no difficulty, Mr. Tredgold imagines, in adopting such a train of mechanism as would produce the alteration of velocity required, and yet be as strong and durable as the ordinary combination, and not at all expensive, compared with the object to be gained by introducing it. It will only be necessary to provide for an increase of velocity: for, when the boat goes with the stream, the rate of the paddles is already too great; whereas, when a boat moves against the current, both an increase of the velocity of the wheel, and an increase of surface of the paddle, is necessary to maintain the mean rate.

Mr. Tredgold concludes his very interesting investigations, by inquiring into the velocity a boat may be expected to acquire when the power is the same. The power P of the engine may be represented, as we have before determined, by the equation

$$P = \frac{a\,v\,(v \mp c)^2}{u^2};$$

and if the ratio of the current to the velocity of the boat be as $1 : n$; that is, $1 : n :: v : c = n\,v$, we shall have

$$P = \frac{a\,v^3\,(1 \mp n)^2}{n^2},$$

$$\text{or, } v = \left(\frac{P\,n^2}{a\,(1 \mp n)^2}\right)^{\frac{1}{3}}.$$

If the boat moves in a current, of which the velocity is n times the velocity of the boat, we shall have

	Velocity of the current with the stream, 4 miles per hour.	Velocity of the Boat, 8 miles per hour.
	2.3	6.6
	1.53	6.12
Still water	0.00	5.00
Against the stream	1.03	4.34
	1.38	4.16
	1.92	3.85
	2.38	3.53
	3.17	3.17

This table shows that a power capable of moving a boat at the rate of five miles per hour, in still water, will only move it at the rate of a little more than three miles per hour against a current of the same velocity as the boat; and that the speed of the same boat would be eight miles per hour, when moving with a current of which the velocity is four miles per hour. It should be remarked, that these calculations suppose the area of the paddles, and their velocity, to be adjusted to the maximum proportions in each case; were it otherwise, the velocity with the current would be increased, and the velocity against the current diminished.

REMARKS.

Just as this paper was going to press, four ships were equipped,* of the respective constructions of Sir Robert Seppings, Professor Inman, Captain Hayes, and Captain Symonds, for the purpose of contesting their relative qualities; and so important does the Board of Admiralty consider the point in question, that an admiral (Sir Thomas Hardy) has been appointed to command the squadron, to direct its various evolutions, and to report on the respective qualities of the ships. It is needless to add how much naval architecture must be ultimately improved by the knowledge to be derived from the many experimental ships that have been lately constructed. It would be a great advantage, however, if each constructer would publish, in a detailed form, *the principles he employs in the formation of his ship.* It is not sufficient to be merely able to construct a good ship. Science requires that we should know *how* and *why* it is a good ship; *what principles have been employed in its construction, and what general rules may be derived from approved individual examples.*

It is not in the terrible season of war, when the hopes and energies of man are principally occupied by conquest, that naval architecture can be expected to make its greatest steps towards perfection. "In war," as the celebrated Dupin observes,† "the object is to do much in a little time, to sacrifice rigorous methods to means ready and expeditious, and the way the best in itself, to the manner most commonly known. At the return of peace, and when a nation begins to feel the benefit of repose, opportunity is afforded for reflection, and extreme rapidity of operation gives place to inquiries into the best methods of executing the details of duty, and of throwing into the practical operations of the ship-builder, some of the genuine principles of science." Let us hope that this great country, which owes its proud and commanding position among the nations of the earth so essentially to its marine, will lose no opportunity of imparting to it every improvement that the enlarged experience of modern times has disclosed; and to prepare it, if the unfortunate destiny of man should so require, for a more splendid and triumphant maintenance of the national honour and glory, than even our former brilliant achievements displayed.

The preceding article is another proof, to the many on record, of the hostile and unjust spirit prevailing among the writers of Britain against the United States. It says, first, that "the Americans have with some unfairness, claimed the original invention of the steam boat." This claim was never made: all that we contend for is, that Robert Fulton first successfully reduced the principle of steam navigation to practice, which had been in vain attempted with profit, before his time. In this position we are supported by cotemporary Encyclopædists, a British engineer, and the report of a Committee of the House of Commons.

1. The supplement to the Encyclopædia Britannica, (Edinburgh 1824,) article Steam Navigation, contains a letter from Mr. Henry Bell of Glasgow, to the editor of the Caledonian Mercury, dated October, 1816, stating that he built the Comet steam boat in 1811, which was the first built in Europe that answered the end; but the editor adds, that "the first American steam boat which completely succeeded, was launched at New York on the 3d October, 1807, five years before the construction of the Comet of Port Glasgow."

2. In the fifth report of the select committee of the House of Commons on steam boats, &c. published in June, 1822, (Sir H. Parnell, Baronet, in the chair,) after tracing the different experiments, from Mr. Hull's, in 1763, to Mr. Symington's, in 1801, it is said, "*Still no practical uses resulted* from any of these attempts. It was not till 1807, when the Americans began to use steam boats upon their rivers, that their safety and utility were first proved. But the whole merit of constructing these boats is due to natives of Great Britain. Mr. Henry Bell, of Glasgow, gave the model of them to Mr. Fulton, and went over to America to assist him in establishing them. Mr. Bell continued to turn his talents to the improving of steam apparatus, and its application to various manufactures about Glasgow, and in 1811 built the Comet

* About eighteen months since, three corvettes, the Pylades, Orestes, and Champion, were constructed respectively by Sir Robert Seppings, Professor Inman, and Captain Hayes, and several experimental cruises made in them. An account of the comparative merits of these ships may be seen in the first number of the work entitled, *Papers on Naval Architecture.*

† Progres des Sciences et des Arts de la Marine Française, depuis la Paix, par Ch. Dupin, à Paris, 1820.

to navigate the Clyde, &c." The editor of the Literary Gazette adds, "This was the *first practical European steam vessel*, and hence has sprung those hundreds of noble ships which convey us and our merchandise to all ports of the empire, with expedition, regularity and economy."

This report, which was made after a strict examination by the Committee, of persons who were capable of affording the most correct information on the subject, is of itself sufficient to establish the particular merit of Mr. Fulton for which we contend, but when added to other facts, no doubt can remain in the mind of any one on the question. No mention, however, is made in Mr. Colden's life of Fulton, of his having received a *model* from Mr. Bell, nor of his having come to the United States to assist Mr. F. in establishing steam boats, and Mr. Bell is also silent on these points in his letter referred to. It is therefore probable that there is a mistake with respect to them. There can be no doubt of Mr. Fulton having greatly profitted by his conversations with Mr. Symington and Mr. Bell; and the last of these gentlemen states that Mr. Fulton wrote to him "that he had constructed a steam boat from the different drawings of machinery he had sent him, but required some improvements on it."* According to Mr. Colden, the engine was made by Messrs. Bolton and Watt, by order.

3. Mr. Buchanan an English engineer, in his "treatise on propelling vessels by steam," admits the claim of Mr. Fulton so far as is contended for him. He says, "In eighteen hundred and seven, Mr. Fulton of New York, introduced steam Boats in America, *which were the first that succeeded in a profitable way*".

II. The writer of the above article admits, that "the honor belongs to Mr. Fulton of having been the first who *endeavoured* to investigate on principle the difficulties of the subjects of steam Navigation," but he had not candour, or liberality enough to say, that the result of this investigation was full success in an object which his own countrymen had not been able to accomplish. Such however is the fact; Mr. Fulton not only ascertained the "difficulties," but removed them, and his countrymen since his death, have improved upon his plans to a most astonishing degree. In proof of this, it is only necessary to compare the speed of steam boats during several years after they were first built, and chiefly on the British plan, by Mr. Fulton, and at the present time. In a letter from Fulton to his friend Joel Barlow, dated August 2d, 1807, he informs him, that "he ran up to Albany in 32 hours, and down in 30 hours."† The first rout was at the rate of a mile in fourteen and a half minutes, and the last at that of five miles per hour.

In August 1826, the steam boat "new Philadelphia," built by the Messrs. Stevens of New York, made an experimental trip from New York to Albany, and performed it in twelve hours and twenty three minutes, part with, and in part against tide. She must have proceeded at the rate of more than thirteen miles an hour, the distance being one hundred and sixty miles.

On the 25th October 1828, the North America made the passage from New York to Albany in ten hours and ten minutes, say 16 miles an hour. During the passage, she stopped at six wharves. The rate of this boat is one mile in four minutes fifty-eight seconds. In November of the same year, the De Witt Clinton made the same trip, and returned to New York in twenty-four hours.

The first boat built at Pittsburg for the New Orleans trade, was in the year 1811, and partook of the slow motion of the original New York boats. Even in 1817, the quickest voyage made from New Orleans to Shippingport, two miles below Louisville, was twenty-two days, and the time required to go down with the current, was from twelve to fourteen days. The passage up is now made in from ten to fourteen days, and less, and down in six days.

On the Mississippi, the rates of going against a strong current, are eight and nine miles an hour, averaging the voyage from New Orleans to Louisville, a distance of 1580 miles, and which was performed by the steam boat Tecumseh in eight days and two hours. In April, 1827, the same boat did it in nine days and four hours, having lost one whole night, and part of another by fog. The boat Huntress made a voyage in May 1827, from and to the same places, in eight days and eleven hours, against a rapid current, though she lost ten hours by a fog. The Pioneer and Columbia performed the same rout in nine days. Twelve years before, this voyage required four months in common river boats. Three or four years since, the De Witt Clinton left Cincinnati, went to Pittsburg, (against a strong current) transacted business there, and returned on the sixth day, a trip of upwards of one thousand miles!

In March, 1827, the steam boat William Tell, made the voyage from Pittsburg to Cincinnati, a distance of five hundred miles, at the rate of thirteen miles per hour.

The steam boat Independence, in May 1829, made the passage from Frenchtown, on Elk river, to Baltimore, a distance of seventy miles, in three hours and a half.

In April, 1829, the steam boat Benjamin Franklin, made the passage from New York to Providence, Rhode Island, dock to dock, in fifteen hours twenty-three minutes: distance, two hundred miles. The rates of sailing of the steam boats up the Delaware, are from one hour and a half to two hours, to Burlington, against tide, and one hour and twenty-three minutes with tide. The shortest passage was one hour nineteen and a half minutes. The distance is twenty miles.

III. The assertion of the writer of the above article, that "the invention of the steam boat is due, both in theory and practice, to Great Britain," is not correct, for the Marquis de Jouffroy, in the year 1781, constructed a steam boat on the Soane at Lyons, 140 feet long, and made several experiments with it;‡ and our countrymen, John Fitch and Henry Voigt, many years before the experiments of Mr. Symington, viz. in 1787, built

* Supplement to the Encyclopædia Britannica, art. Steam Navigation.

† Colden's life of Fulton. The reader is referred to this interesting work, for a detail of various plans of steam boats in Europe, the difficulties that occurred, and the progressive experiments by Mr. Livingston and Mr. Fulton, which finally led the latter to the adoption of the water wheels at present in use, as propellers.

‡ Supplement to the Encyclopædia Britannica, article Steam Navigation.

a steam boat at Philadelphia,* by subscription, and worked it by paddles. This boat went to Burlington 20 miles up the Delaware, and returned the same day, having the Governor, (Gen. Mifflin,) and many other citizens on board. The manuscripts of Mr. Fitch bequeathed by him to the Library Company of Philadelphia, contain the certificates of several distinguished men of their having gone in the boat at the rate of six miles per hour, several times between the year just mentioned, and 1791. Among these were David Rittenhouse, Dr. John Ewing, Provost, and Robert Patterson, Professor of Mathematics in the University of Pennsylvania, Andrew Ellicott, and others: but it appears that some defect was discovered, or some improvement was suggested in almost every experiment, which occasioned him to make such repeated draughts upon the company, that their patience became exhausted, and the members despairing of ultimate success, and being probably influenced by the unceasing ridicule cast on the project, refused to furnish the funds occasionally required, and gradually withdrew from the concern. The one he most regretted, was Mr. Voigt, to whose mechanical ingenuity, he had been greatly indebted. The debts incurred by Mr. Fitch on account of repairs for the boat, his inability to discharge them, and to obtain the means to proceed with his experiment, obliged him finally to abandon it, after years spent in the greatest anxiety for its completion, and of the most praiseworthy industry, and heroic perseverance to bring it to perfection. If Fulton had been placed in the same circumstances with Mr. Fitch, he would have been defeated from a similar cause, and but for the liberality of Robert R. Livingston, the world might have been, even at the present day, without a steam boat! The following document, written by one of the early patrons of Mr. Fitch, will throw light on the subject.

From the London Monthly Magazine of Oct. 1815.

"*A short account of the origin of steam boats, by Dr. Thornton, director of the patent office Washington.*

Finding that Mr. Robert Fulton, whose genius and talents I highly respect, has been by some considered as the inventor of the Steam Boat, I think it a duty to the memory of the late John Fitch, to set forth, with as much brevity as possible, the fallacy of this opinion; and to show, moreover, that if Mr. Fulton has any claim whatever to originality, in his steam boat, it must be exceedingly limited.

In the year 1788, the late John Fitch applied for, and obtained, a patent for the application of steam to navigation, in the states of Pennsylvania, New York, New Jersey, Delaware, &c. and soon after, the late Mr. James Rumsey, conceiving he had made some discoveries in perfecting the same, applied to the State of Pennsylvania for a patent; but a company formed by John Fitch, under his state patents, of which the author of this was one of the principal share-holders, conceiving that the patent of Fitch was not for any peculiar mode of applying the steam to navigation, but that it extended to all known modes of propelling boats and vessels, contested before the assembly of Pennsylvania, and also before the assembly of Delaware, the mode proposed by Mr. Rumsey, and contended that the mode he proposed, viz. by drawing up the water into a tube, and forcing the same water out at the stern of the vessel or boat, which was derived from Dr. Franklin's works (the doctor being one of his company) was a mode they (Fitch's company) had a right to, for the plan was originally published in Latin, about fifty years before, in the works of Bernoulli the younger; and two of Fitch's company and I appeared without counsel, and pleaded our own cause in the assembly, of Pennsylvania, (the hon. Messrs. Findley and Smiley, of Congress, were then sitting members of the assembly;) and, after a week's patient hearing against the most learned counsel of Pennsylvania, we obtained a decision in our favour, and afterwards also in Delaware. We believed, and contended, that our claim of propelling boats by steam, included all the modes of propelling vessels and boats then known, and that the patent was for the application of steam as an agent to the propelling powers; and the decisions of the legislatures were in favour of this construction, as Mr. Rumsey's company (of which the late Messrs. Bingham, Myers Fisher, and many other worthy gentlemen were members) were excluded from the right of using steam boats on any principle.

We worked incessantly at the boat to bring it to perfection, and some account of our labours may be seen in the Travels of Brissot de Warville, in the U. States; and, under the disadvantages of never having seen a steam engine on the principles contemplated, of not having a single engineer in our company or pay, we made engineers of common blacksmiths; and, after expending many thousand dollars, the boat did not exceed three miles an hour. Finding great unwillingness, in many, to proceed, I proposed to the company, to give up to any one the one half of my shares, who would, at his own expense make a boat go at the rate of eight miles an hour, in dead water, in 18 months, or forfeit all the expenditures on failing; or I would engage with any others to accept these terms. Each relinquished one half his shares, by making the 40 shares eighty, and holding only as many of the new shares as he held of the old ones, and then subscribed as far as he thought proper to enter on the terms: by which many relinquished one half. I was among the number who proceeded, and in less than 12 months we were ready for the experiment. The day was appointed, and the experiment made in the following manner. A mile was measured in Front street (or Water street) Philadelphia, and the bounds projected at right angles, as exactly as could be to the wharfs, where a flag was placed at each end, and also a stop-watch. The boat was ordered under way at dead water, or when the tide was found to be without movement; as the boat passed one flag it was struck, and at the same instant the watches were set off: as the boat reached the other flag it was also struck, and the watches instantly stopped. Every precaution was taken before witnesses: the time was shewn to all; the experiment declared to be fairly made, and the boat was found to go at the rate of eight miles an hour, or one mile within the eighth of an hour; on which the shares were signed over with great satisfaction, by the rest of the company. It afterwards went eighty miles in a day!

The governor and council of Pennsylvania were so

* The boat was 60 feet long, 8 feet wide, and 4 feet deep.

highly gratified with our labours, that, without their intentions being previously known to us, Governor Mifflin, attended by the council in procession, presented to the company, and placed in the boat a superb silk flag, prepared expressly, and containing the arms of Pennsylvania, and this flag we possessed till Mr. Fitch was sent to France by the company, at the request of Aaron Vail, esq. our consul at L'Orient, who, being one of the company, was solicitous to have steam boats built in France. John Fitch took the flag, unknown to the company, and presented it to the national convention. Mr. Vail, finding the workmen all put into requisition, and that none could be obtained to build the boats, paid the expenses of Mr. Fitch, who returned to the United States; and Mr. Vail, afterwards, subjected to the examination of Mr. Fulton, when in France, the papers and designs of the steam boat appertaining to the company."

In the year 1827, there were 109 steam boats of the burthen of 18,597 tons employed in the trade of the Ohio, and Mississippi rivers. The greatest is of the burthen of 375 tons; the average is about 170 tons. In 1826, 35 were plying from New York up the Hudson, and to Connecticut, Rhode Island, and to New Jersey, besides seven steam ferry boats; there were 17 on the Delaware, and 9 or 10 on the Chesapeake.

Upon Lake Erie, the following steam boats were plying in the year 1826:

Superior,	built at Buffalo, New York,	-	346 Tons.
Henry Clay,	" Black Rock, do.	-	300
Niagara,	" do. do.	-	200
Pioneer,	" do. do.	-	150
Enterprise,	" Cleaveland, Ohio,	-	200
William Penn,	" Erie, Pa. - -	-	200
Chippewa,	" Buffalo - -	-	100

Statement showing the amount of steam boat tonnage of each State and Territory of the United States; also, the duty collected on the same, during the year 1827.

Treasury Department,
Register's Office, April 15th, 1828.

JOSEPH NOURSE, Register.

Twenty-two steam boats were built in the city and vicinity of Pittsburg, within twelve months preceding March 1829. Their aggregate tonnage was 4570 tons.

The steam boats of the United States are distinguished for their neatness, and comfortable accommodations; and many of them are fitted up in the most elegant style, contributing thereby to the health, and pleasure of the passengers.

SHOE MACHINERY. The machines for making shoes, of which we propose to give a brief and general account, were invented by the celebrated engineer Mr. Brunel, with whose ingenious inventions our readers are already well acquainted.

During the late war Mr. Brunel established at Battersea Bridge his machinery for making shoes, principally with the object of supplying the army. The machines were all managed by the invalids of Chelsea Hospital, who were unfit for any other employment.

In shoes of the usual kind the sole was united to the upper leather by sewing, but in the year 1809, Mr. David Mead Randolph, an American, took out a patent for employing rivetting in place of sewing in fixing the soles and heels of shoes to the upper leather. This method was adopted by Mr. Brunel, but he also extended it to all the parts of which the shoe is composed.

The shoes made by this machinery are composed of the following pieces:

1. The upper leather, consisting of three pieces, viz. the *vamp*, or the portion which covers the upper part of the foot, and the two quarters which run round the heel. These three pieces are sewed to one another.

2. The sole part of the shoe, which consists of the real or lower sole with its welt, the heel, and the inner or upper sole. The welt is a running border, fixed by a row of nails on the upper side of the lower sole, so as to increase the thickness of the sole towards its edge, and it lessens gradually inwards.

The upper leathers are made of sufficient size to turn in all round beneath the foot under the edge of the inner sole, for about $\frac{3}{4}$ths of an inch wide, and the inner sole, with its welt, is applied beneath so that the turning in of the upper leather is included between the two soles.

The nails used to fasten together the different parts are as follows:

1. The *long nails*, which form a complete row as near as possible to the edge of the whole shoe, passing through the two soles, the welt, and the upper leather. The heel is also fastened on by a row of these nails round its edge. The heads or thick ends of the nails are seen on the lower side of the soles, and keep the leather from wearing.

2. The *tacking nails*, which are such a size as to pass only through the sole and the welt. Of these there is a row all round the edge of the foot, but farther from the edge than the row of long nails.

3. The *short nails*, which only penetrate through the thickness of the lower sole. These are disposed in parallel rows across the tread of the foot, and also in a double row parallel to the outline of the toe, at about $\frac{3}{4}$ths of an inch from the edge.

The machines which are employed in manufacturing the shoe may be arranged as follows:

1. The cutting up machine.
2. The compressing machine, for pressing the soles.
3. The machine for punching the holes.
4. The machine for cutting the short nails, and inserting them.
5. The machine for punching the long nail holes and inserting the long nails in the holes.

6. The welting stand.
7. The cutting press.
8. The clamping machine.
9. The machine for cutting the long nails.

1. *The machine for cutting out the leather.* The various pieces of leather which compose the shoe are cut out by stamps, each of which is an iron frame or ring bent to the shape of the piece to be cut. The sharp edge of these stamps being placed upon the skin, and struck with a wooden mallet, will cut out the leather of the same form. The leather for the soles being softened, is laid on a table of lead, about two feet long, and one and a half wide, and is cut in a similar manner.

The inner soles are cut by a machine of the following construction. The stamp or knife is placed horizontally, with its sharp edge upwards, and the sole simply cut by a common knife round a wooden pattern, is laid upon the stamp. A lever, with a plate of lead fastened near its fulcrum, is fixed on the frame which supports the knife. The lever being now brought down by the hand, presses the plate of lead upon the sole, and thus enables the stamp to cut it out of the exact shape.

The welts, which must be cut out into strips of an inch wide, are made in a quite different manner. The leather is extended on a flat wooden table, two feet square, having its surface covered with small iron rulers, whose width is equal to that of the strips of leather to be cut, and screwed down upon the table, sufficient spaces being left between the rulers to admit the point of a knife. From these rulers several small pins project upwards, which passing through the leather, hold it firm. An iron frame, fixed to the table by hinges, folds down horizontally upon the leather, and is furnished with similar rulers, whose intervals correspond exactly with those between the fixed rulers, so that the whole leather is divided into strips of the same breadth as the rulers, which are cut out by introducing the point of a hooked knife between the rulers.

Each of these slips is now to be cut lengthwise into two, by an oblique or bevelled cut, and this is done by the following machine. This machine consists of a pair of brass rollers, one of which, turned by a wheel, gives motion to the other by a pair of equal cog-wheels, one wheel being fixed on the end of each roller. The rollers are placed one above another in an iron frame, the lower one having a groove cut round it to receive the strip of leather previous to its being divided. The upper roller serves to press the strip of leather into the groove. The leather is guided into the groove through a square hole in an iron stem fixed in front of the rollers. On the other side of the rollers is fixed a fine sharp steel edge, which being placed obliquely to the surface of the leather, cuts it into two slips with bevelled edges, or it passes through the rollers. The texture of the leather is also improved by the pressure of the rollers.

2. *Compressing machines for preparing the soles.* This machine supplies the place of hammering. It consists of two brass rollers, about five inches long, and five inches in diameter, mounted like the common laminating roller. Instead of screws, however, which are usually employed to hold down the upper roller, and adjust it to the proper distance from the lower one, two plain cylindrical pins are put into the holes where the screws would have gone, and upon the upper one the power of a strong lever, with a weight, is applied, giving a pressure of 1200 pounds. At the end of the axis of the lower roller is a cog wheel, driven by a pinion on the end of an axis turned by a winch handle. One works at the winch while another puts two soles, with the flesh sides together, between the rollers. An iron plate, with thin edges, is placed between the soles, which are passed backwards and forwards four or five times, till they are brought to the proper hardness and solidity.

The heel pieces are too small for this operation, but they are put into a small cell of cast iron, with an iron plate laid above them, and then subjected to the powerful pressure of a single blow of a screw press.

The heel pieces and the soles are bevelled at the place where they are to be joined, so that when they are united by three or four nails the whole is equally thick. The joints are cut to the proper bevel by a single press. The sole is laid flat on the bevelled edge of a bench faced with iron, and a piece of iron is pressed down upon it by the workman's elbow; the knife is thus properly guided to make the bevelled cut.

3. *The machine for piercing the holes.* This machine consists of a semicircular table of cast iron, supported by a column two feet high, which is connected by a projecting iron bracket to the table, which is thus placed between the workman and the column. Two arms project over the table from the column, and have their extremities formed into sockets, in order to support and allow to descend through them a vertical square iron slider, into the lower end of which is screwed the piercer. From a treadle moving on a centre pin fixed to the foot of the iron column, there rises an iron rod through a hole in the table, and also through holes in the projecting arm, and at the upper end this rod is joined to a lever moving on a joint at the upper end of the iron column, while the extremity of the lever is connected with the top of the perpendicular slider. When the foot of the workman presses upon the treadle, the slider and piercer are forced down towards the table, but never so far as to touch it, and these are raised up again without any effort, by means of a counterpoise and short lever.

The next part of the apparatus is an iron plate or pattern, of the size and shape of the sole, which is united to it by two sharp guage pins fixed in the pattern. The pattern is perforated with the same number of holes which it is proposed to make in the sole. The pattern, with the sole united to it, is laid on the iron table with the leather uppermost, and brought to a place where an iron stud rising through a hole in the table, and immediately beneath the piercer, enters every one of the holes of the pattern. The stud being only held up by a spring, is easily pressed down if the point of the piercer should, after penetrating the leather, happen to come down upon the stud. In this way any number of holes may be pierced merely by putting the stud into the holes of the iron pattern. A small piece of iron is fixed immediately above the leather, which prevents it from being lifted up along with the piercer. There is of course a hole in this piece of iron, through which the piercer moves.

4. *The machine for cutting the short nails, and inserting them in the holes.* The apparatus for cutting the nails forms the upper part of the machine. The

shears for cutting the nail consists of a loaded lever connected with a treadle. The lever has a cutter near its centre, so that when the foot depresses the treadle the leaver is raised, and cuts against the edge of a hard cutter. A slip of iron being introduced between the cutters, has a small piece or nail cut off from the end of it. This nail, the instant it is cut, falls into a tube, by which it is conveyed to a small tube over the leather, where it is ready for a subsequent operation.

The pattern, or iron plate, with the sole fixed to it, is now again used, and is brought by the method formerly directed, under a blunt piercer, which descends by the action of the treadle. The workman now bringing a hole beneath the piercer, holds a sheet of iron or copper, and pushes it between the open shears, then depressing the treadle, the nail in the tube is forced down by the piercer into its hole in the leather. At the instant that the nail falls into the leather, the shears close and cut off a new nail, which falls as formerly into a new hole which the operation has wrought beneath it. At every cut the sheet of copper is turned over, in order to form the nails alternately head and point. When all the nails have been inserted, they are beaten down with a hammer.

5. *Machine for punching the long nail holes, and inserting the long nails in the holes.* This machine is exactly like the punching machine already described, but it is furnished with additional apparatus to supply the nails and convey them into the holes. These additional parts are a circular brass wheel, nine inches in diameter, and nearly as thick as the nails are long. Great numbers of holes are perforated in it, and arranged closely in four circles, one within another. The central point within the four circles of holes has six radii like the spokes of a wheel, and in the very centre is a bolt, which fits loosely upon an upright centre pin, placed in the centre of a small circular table fixed laterally to the upper projecting arm which holds the upper end of the perpendicular slider. The wheel being fixed horizontally, about 18 inches above the table which holds the sole, has a nail put into every hole in its four circles. The holes are large enough to allow the nails to drop through them, but the points rest upon the circular table, at one part of the circumference of which an opening is cut through it, and a small tube descends from the opening to conduct a nail down to the point of the piercer. By the revolution of the wheel, the nails are brought successively over the mouth of the tube, so that each falls with its point downward into a small cell exactly beneath the point of the piercer when at its highest position. By depressing the piercer with the treadle, it forces the nail through the cell into the hole in the leather, brought beneath it in the form and manner formerly described. The construction of this cell deserves particular notice. It is conical inside, but when the nail which it grasps is to be forced down by the piercer, the cell opens in two halves, being formed by semiconical notches in two pieces of steel, which are held together only by being screwed together at one end. They are made so thin as to spring together to form the conical cell. While the piercer is ascending, another nail drops from the wheel through the tube into the space or open joint at which the two halves of the cell separate, so that the nail lies close beside the piercer. As soon as the piercer has risen out of the cell its two halves spring together, and the space containing the nail having its faces inclined inwards, these faces throw the nail into the cell, where it sticks till the piercer descends to drive it into the leather.

In order that the circular wheel may furnish a fresh nail after the preceding one has been inserted, the edge of the wheel has serrated teeth equal to the number of holes in each of the four circles. A detent tooth goes into these teeth by a hook, so that it will turn the wheel when moved in one direction, but slip over them when turned in the other direction. The detent tooth is jointed to a short lever fixed to the upper end of an upright axis, which, passing downwards through the projecting arms of the main columns, so as to be as near as possible to the perpendicular slider, and a short lever attached to this axis, is kept by a spring against a wedge fixed to the slider. When the slider, therefore, descends, its wedge forces away from it the end of the short lever. This movement is conveyed by the upright axis and upper lever to the detent tooth which slides over the inclined sides of the teeth of the wheel. When the slide reascends, the wedge permits the lever and detent tooth to return to the action of a spring; and a hook of the detent catching a tooth of the wheel turns it round through the space of one tooth or the distance between two nails. When the nails are all put in they are beat down with a hammer, so as to drive all their heads to a level with the surface, leaving the points projecting through the leather. The sole is then severed from the iron pattern, and put into the welting stand.

6. *The welting stand.* A small square cast iron table is fixed upon the top of a pedestal so as to turn round upon it; an iron frame is connected with the table by hinges on one side, so that it can be made to rise from it, or to lie flat upon it, and in this situation it may be fixed by a clamp. This frame has an opening in it nearly of the same shape as the sole of the shoe which is placed flat on the table, so that when the iron frame is brought down upon it and the clamp fixed, it encloses the sole as it were with an iron hoop or elevated border. The sole is now lying as it were at the bottom of a cell of iron, with the projecting points of the nails upwards. The welt is now applied by laying the strip of leather upon the edge of the sole, and binding it so as to follow the outline of the sole. Whenever any part of the welt is placed in its position, it is struck down upon the sole with a mallet, which draws it upon the points of the nails. When the welt is brought quite round the sole and heel, it is bevelled at its extremities, which thus form a joint without any increase of thickness. The welt and sole being well beat together, they are next carried to the cutting press, by which the edge of the sole and welt are cut precisely and exactly to the same size. Previous to this operation, the sole is confined between two iron patterns, made exactly of the size to which the sole is to be formed.

7. *The cutting press.* A horizontal spindle, like that of a turning lathe, passes through two standards rising from a horizontal plate. It goes through a collar in one standard, projecting some inches beyond it, and carries at its extremity a piece of wood with a flat surface, and of the same shape as the sole. The sole between the two iron plates is pressed against

this flat surface by a screw fitted into an iron standard rising from the same horizontal plate, and pressing by the intervention of a lever upon the iron plates opposite to the end of the spindle. By this pressure the spindle retreats in the direction of its length a small quantity: and in consequence of this, a flat circular plate, fixed upon the spindle like the pulley of a lathe, presses against a similar flat plate fixed to the frame, and unable to turn. The spindle becomes immoveable by the friction of these two surfaces, and the sole is kept firm in the press, while the workman with a drawing knife, worked by both hands, cuts the edge all round. After having pared the uppermost part of the edge, he releases the screw of the press, and the spindle, pressed forward by a spring, advances and separates the friction plates. The spindle with its sole being turned round, a fresh part of the edge is pared, and so on till the whole is finished. The edge of the sole thus cut is then ground smoothly on a rapidly revolving grindstone, and polished on a wooden wheel with a little bees wax spread upon it.

8. *The clamping machine.* The object of this machine is to close or rivet the shoe together. The upper leather being put upon a last, is fixed with its sole upwards about six inches above a small oval table, capable of turning round upon the column which supports it. The sole of the last is a solid piece of cast iron, but the lower part which receives the upper leather is of wood. The last is then fixed firmly on the table by two steady pins, and by a strong pin projecting downwards through the table, and confined by a wedge. To the oval table are attached a number of pieces of brass by hinges, which are so arranged round the last that they can be bound up against the upper leather, and form clamps, which, when they are all up, form a complete cell or box embracing the upper leather. Each clamp is forced into its situation by an independent screw, tapped obliquely through the edge of the table, and pressing up by its point the end of a small rod jointed to the clamp, near the part where it presses upon the leather. By releasing this screw, the clamp turns back on its hinge and falls back upon the table. The inner sole of the shoe being fastened to the sole of the last by two short pins, one in the sole and the other in the heel, the upper leathers are put on in their true position, and the last is fixed in its place in the middle of the clamping table. The clamps are now turned up, and the upper leathers drawn up all round with a pair of pincers, so as to fit them to the last; the clamps are screwed tight up. The edges of the upper leather are now turned over, and the operation is carried on as in common shoemaking till the sole is put on. The nail which fastens the inner sole to the last is now drawn out, the real sole is applied and put in its proper place by an iron frame or saddle. This frame, which is of thin iron, has its inside figure of the same size as the row of rivetting nails which project through the sole. It is made in two halves, united by a hinge at the heel part, and there are two holes at the toe in which a pin can be put to hold the frame together. This pin, and the joint pin of the hinge at the heel, projects far enough into a hole in each of the two clamps at the toe and heel, so as to guide the frame into its proper position.

When all the long nails are inserted in the soles by the machine already described, it is put into an iron box, and by a blow of the fly press it is made concave inside so as to fit the last. When taken from this mould, the inner frame is put together round the row of nails, the inside of the frame just receiving the projecting points of the nails so as to keep them perpendicular to the leather, and prevent them from spreading out. The sole being then applied by the guide pins of the frame, and the heads of the nails struck, their points penetrate through the turned in upper leather and the inner sole. When they are well entered, the iron frame is removed by opening it at its hinge, and the nails are driven down into their places. The nail points fall into a slight semicircular groove round the sole and the last, which turns their points all the same way. The last being taken out of the shoe, which is easily done from the heel of the last being made in a separate piece, the shoe is carried to the rivetting last, without a semicircular groove, upon which it is beaten, so as to rivet all fast, and smooth the sole inside. The heel is then put on in its place, and the long nails put through its holes by the nailing machine, and driven down in the same way as for the sole.

All the nail heads are now levelled with a rasp, the shoe is ground and polished up with a composition of bees wax and ivory black, the upper leathers being brushed with a circular brush, and the shoes made ready for sale, except those which require to be bound and lined.

The machine for cutting the long nails. The nails are cut from slips of sheet-iron, which is so cut, that when the nails are cut off from the end of the slips, the grain of the iron will be in the direction of the length of the nail.

In cutting the nails, the workman applies the iron with his hand, and draws the machine, by the action of his foot upon a treadle; the treadle drives a crank and heavy fly; from the crank there proceeds a rod to the longer end of a strong lever, whose axis is supported on pivots above the fly and the crank. A fixed cutter being attached to the frame, a steal cutter, which acts against it, is fixed at a small distance from the centre of the lever, and at the opposite side of the axis to the long lever. This cutter is sharpened on the lower side, and the fixed one on the upper side. As the lever rises and falls by the revolution of the crank, the edge of the moveable cutter is brought close to that of the fixed one without touching it. The slip of iron being admitted between the cutters, a small portion of the end of it hangs over the edge of the fixed cutter, and is cut off into a nail by the descent of the fixed cutter. On the ascent of the moveable cutter, the strip of iron is pushed forward, and another nail is cut. The nails are narrow at the end which is to be the point, but at the other end they are as broad as the thickness of the plate, so as to have a square figure. In the direction of the thickness of the plate, they are as broad at the point as at the head, so that the nail is a small wedge instead of a pyramid. For this purpose the cut across the slip of iron is not perpendicular to the length of the strip of iron, but a little inclined to it; and as the inclination of the cut is reversed at every successive cut, the head of one nail is cut from the same side as the point of the next. The thickness of the nail is regulated by the quantity by which the extremity of the slip of iron projects over the edge of the fixed cutter, and the angle of inclination may be made to vary by two stops, against which the end of the slip bears. This is effected by a part projecting from the lever beneath the edge of the moving cutter, and curved to the arc of a circle described from the axis. This slip is as far behind the edge of the cutter as the thickness of the nail intended to be cut off. The reversing of the cut is effected merely by turning the under side of the slip uppermost after every cut.

We have been induced to give this particular account of the shoe machinery, not merely from the ingenuity displayed in its construction, but from the probability of its being, with some modifications, more extensively employed in various branches of the useful arts. Several of the machines above described were executed by Mr. Henry Maudslay with that ingenuity and accuracy which characterise all his works.

SHOEING. See Veterinary Surgery.

SHOREHAM, New, a market and borough town of England, in the county of Sussex, is situated on the coast of the English channel, and about a mile west of the harbour on the river Adur. It consists chiefly of one street parallel to the river, which is crossed by long wooden bridge. The principal public buildings are the church, market-house, custom-house, and town-hall. The church, which has been lately repaired and beautified, is an interesting specimen of Norman architecture. As the nave to the west ol the tower had been destroyed, the east part only was formerly fitted up for divine service. It appears to have been built about the end of the twelfth century. There is much elegance, richness, and variety, in the architectural details within. The market-house, situated in the middle of the town, is supported by Doric columns. The harbour, which is a tide one, is not good. In spring-tides it has about 18 feet of water, about 12 in common tides, but only 3 at ebb tide. The town has nevertheless a custom-house, and ships of considerable burden come up to the town. Shipbuilding is the chief business carried on in the town; vessels of 700 tons have been launched here. The trade of the place is limited to a little coasting trade, and to the mackerel and herring fishery. The river is navigable for barges as high as Steyning, from which large quantities of timber are brought down for the dock-yards. The borough is governed by two constables annually elected. It sends two members to Parliament, elected by about 1300 voters, every forty-shilling freeholder within the rape of Bramber being entitled to vote. Population about 800. See the *Beauties of England and Wales*, vol. xiv.

SHORTSIGHTEDNESS. See Optics.

SHORT, James, a celebrated Scottish optician, was born at Edinburgh, on the 10th of June, in the year 1710. Having lost both his parents at the age of 10, he was received into Heriot's Hospital, where he exhibited his mechanical talents in constructing bookcases with a knife and the few tools which fell in his way. After remaining there two years, he went to the High School to receive a classical education; and in 1726, he entered the University, where, after following the usual course of instruction, he took the degree of M. A.

His friends were desirous that he should enter the church, and with this view he attended a course of theological lectures; but his passion for mathematics and mechanics withdrew him from his theological studies, and soon engrossed all his time and attention. Mr. Maclaurin, under whom young Short had studied mathematics, saw the bent of his mind, and encouraged him to prosecute his studies and mathematical pursuits as a profession. He accordingly began in 1732 to make reflecting telescopes, and the progress which he made will be best described in the following letter to Dr. Smith from Mr. Maclaurin, dated December 28, 1734.

"Mr. Short, an ingenious person, well versed in the theory and practice of making telescopes, has improved the reflecting ones so much, that I am fully satisfied he has far outdone what has yet been executed in this kind.

He has not only succeeded in giving so true a figure to his speculums of glass quicksilvered behind, as to make the image from them perfectly distinct, but has made telescopes with metal speculums, which far surpass those I have seen of any other workman.

He has made six reflecting telescopes with glass speculums, three of 15 inches focal distance. and three of 9 inches. One of the first is at present in my Lord Islay's hands, with which it is easy to read in the Philosophical Transactions, at the distance of 230 feet. Another of them is in the hands of Mr. *Alexander Bayne*, our professor of Law, with which he easily reads the Philosophical Transactions at the distance of 280 feet. I made some trials with one of the speculums of nine inches, and can read with it very easily in the Philosophical Transactions at the distance of 138 feet; but at that time had not an opportunity to try it at a greater distance. At another time I read with it a much smaller print cross the street, at the distance of 125 feet. It cost him a great deal of trouble to make these of a true figure, and with parallel surfaces, and several, when finished, were found useless by reason of veins that then appeared in the glass.

In the glass speculums every thing else was very well, only the light was somewhat faint compared with that reflected from his metal speculums. This I take to have been owing to the speculums not having been well quicksilvered, and partly to the thickness of the glass. For one of them, I observed, had a brighter reflection, when fluid quicksilver was applied to its back surface than after it was foiled.

After he found the light in these glass speculums fainter than he expected, and also because of the great difficulties in finishing them, he applied himself to improve the telescopes with metal speculums. By taking care of the figure, he finds himself able to give them larger apertures than other workmen do; and, by adjusting the speculums and the whole instrument, he has much improved it.

He executes every part himself, and takes vast pains to make the instruments as perfect as possible, and has made them of focal distances of two inches and six-tenths, of four inches, of six inches, of nine inches, and of fifteen inches. He perforates the large speculums, and uses a concave little speculum.

By those of four inches focal distance he saw the satellites of Jupiter very well, and read in the Philosophical Transactions at above 125 feet distance. By those of six inches focal distance he read at 160 feet distance. By those of nine inches focal distance he read at 220 feet distance. By those of fifteen inches, he and Mr. Bayne have read in the Transactions at 500 feet distance, and have several times seen the five satellities of Saturn together, particularly on the 24th of November and the 7th of December last; which very much surprised me, till I found that Mr. Cassini had sometimes seen them all with a seventeen foot refracting telescope.

I have compared some of these with such as have been brought from *London*, and find one of Mr. Short's, of six inches focal distance, compared with one of the best I have seen from London, of nine inches and three-tenths focal distance, to exceed it in brightness, distinctness, and magnifying power; and when I called an indifferent person, who knew not who had made the instrument, to give his opinion, he very readily preferred that of six inches focal distance. It also manifestly exceeded another I had from London, of eleven inches and a half focal distance. The same was the result of some other comparisons.

Upon the whole, I am convinced he has much improved this excellent invention, and that his instruments are by far the best of their lengths that have yet been executed."

In 1736 Mr. Short was invited to London by Queen Caroline to give mathematical instructions to William Duke of Cumberland, and he was soon after elected a Fellow of the Royal Society, to whose Transactions he contributed several valuable papers. In 1739 he accompanied the Earl of Morton to the Orkney Islands where he was employed in a geographical survey of that part of Scotland.

Upon his return to London, Mr. Short established himself as an optician, and in 1742, he was employed by Lord Thomas Spencer to make for him a reflector of 12 feet focal length, for which he received 600 guineas. He soon executed several other instruments with different improvements, and in 1752, he completed one for the king of Spain, which cost £1200. Mr. Short paid two or three visits to Scotland, the last of which was in 1766. After a short illness, he died of a mortification of his bowels, at Newington Butts, near London, on the 15th June, 1768, in the fifty-eighth year of his age. He left a fortune of about £20,000, about £15,000 of which was bequeathed to two nephews, and the rest in legacies. To Lady Mary Douglas, the daughter of his patron, the Earl of Morton, he left £1000, and the reversion of his fortune, if his nephews died without issue; but this lady, at the desire of her father, relinquished the reversion by a deed in favour of Mr. Short's brother, Mr. Thomas Short, and his children.

SHOVEL, Sir Cloudsley, a celebrated British naval officer, was born about the year 1650, of humble parents. Having been for some time apprenticed to a shoemaker, he took a dislike to his profession, and went to sea as a cabin boy under the patronage of Sir John Narborough. By his talents and industry he became an able seaman; he obtained promotion through the interest of Sir Christopher Myngs. Having distinguished himself under Sir John Narborough, in burning the ships of the Dey of Tripoli in 1672,—an enterprise with which he was intrusted,—he was soon after appointed to the Sapphire, a fifth rate, and subsequently to the James galley, a fourth rate, in which he continued till the death of Charles II.

At the time of the revolution, Captain Shovel commanded the Dover, a fourth rate. At the battle of Bantry bay, where he commanded the Edgar, he distinguished himself so much, that King William conferred upon him the honour of knighthood. In 1690, he was employed to convey the king and his army to Ireland, and he was on that occasion appointed rear-admiral of the blue, and his commission delivered to him by the king himself. In 1691, he accompanied the king to Holland; and in 1692, he was made rear-admiral of the red, and a second time attended his sovereign to Holland. Upon his return he joined rear-admiral Russel with the grand fleet, and shared in the glory of the battle of La Hogue. In the expedition to Camaret bay under Lord Berkeley in 1694, he embarked the forces with great skill in that unlucky expedition. In the same year he bombarded Dieppe, Dunkirk, and other places on the French coast. In 1702, he went to Riga to bring home the spoils of the French and Spanish fleet.

In 1703 he had the command of the grand fleet in the Mediterranean, and exerted himself in aiding the Protestants who were in arms in the Cevennes. Owing to the great share which he had in the victory of the 13th April, 1708, he was in January 1709 appointed rear-admiral of the fleet of England, and in the same year he commanded, along with the earls of Peterborough and Monmouth, the fleet which was sent to the Mediterranean. After aiding in the reduction of Barcelona, he made an unsuccessful attempt upon Toulon, and sailed for Gibraltar, where he left a sufficient force for the defence of the coast of Italy. From Gibraltar he set sail for England with ten ships of the line, five frigates, four fire ships, a sloop, and a yacht. On the 22d October, 1707, he came to soundings, and next morning he had ninety fathoms water. About noon he lay by, but about six P. M. believing he saw the light on St. Agnes, one of the Scilly Islands, he set sail again. Soon afterwards several of his ships made signals of distress. The Royal Anne, with Sir George Byng, with difficulty saved herself. Several others encountered the most imminent perils, but the admiral's ship and some others perished with all on board. The body of Sir Cloudsley Shovel was cast ashore next day on the island of Scilly. The fishermen stripped and buried it, and took an enamelled ring from his finger, which proved the means of discovering the body of the gallant admiral. It was accordingly disinterred, and deposited with great solemnity in Westminster Abbey, where a magnificent monument of white marble was erected to his memory, by order of Queen Anne. The fate of this distinguished man, however, who was cut off in the fifty-seventh year of his age, was lamented by the whole nation. See Campbell's *Lives of the Admirals*.

SHREWSBURY, a borough and market town of England, in Shropshire, is situated on two gentle eminences, which are surrounded on all sides but the north by the river Severn. At this open part of the peninsula, a junction is formed on the north-east with the Shrewsbury Canal, and on the north west with the Ellesmere Canal. On the north and west sides, the streets approach close to the river, but in other points a strip of meadow or garden ground separates the houses from the river. An uninterrupted range of well-built houses, commanding beautiful and extensive views, encircles the town, and on the western side is a noble field of twenty acres, called the Quarry, ornamented with columns of trees. The interior appearance of the town is of a different character. The streets are ill arranged, and are in general narrow, steep, and badly paved. The eaves of the old houses project so as almost to meet those on the opposite side; and the mixture of ancient and modern buildings produces a disagreeable effect.

The principal public buildings are the castle, the town-hall, the five churches, the town and county gaol and bridewell, the market house, the theatres, the bridges, and charitable institutions.

The castle occupies a neck of land about 500 yards broad. The buildings which remain, are the keep, the walls of the inner court, and the great arch of the interior gateway. The keep is now a handsome dwelling house, composed of two round towers embattled and pierced, and connected by a square building about 100 feet long and 100 feet high; the inner court is now a garden, and the arch of the gateway is eighteen feet high. A few traces of the ramparts and walls which defended the town on its north and east sides still remain.

The *town-hall* is a modern building, completed in 1786. It has a handsome stone front. In the grand jury room are portraits of George I. and II., and Admiral Benbow; and in another room is a valuable collection of books.

The *churches* on the establishment, are St. Giles', St. Chad's, St. Mary's, St. Alkmund's, and St. Julian's. St. Giles, consisting of a noble chancel and north aisle, seems to have been partly built in the Norman era. St. Chad's church, built in 1791 of freestone, is, generally speaking, a splendid and well-ornamented structure; the body of it is externally a circle 100 feet in diameter. St. Mary's church, in the north-east part of the town, is a large venerable building, in the form of a cross, with a nave, side aisles, transept, choir and chapels, and with a tower at the west end. At the extremity of the chancel is a spacious window, nearly filled with stained glass. From the ruins of old St. Chad's church near the town, which is very large, and seventy-four feet in height, there rises a lofty and beautiful spire, which is a great ornament to the town. The height of the tower and the spire is 212 feet. The monuments in the church are numerous and some of them curious. St. Alkmund's church is built on the site of the old one taken down in 1793. It is an unseemly imitation of the ancient pointed architecture. The church of St. Julian is a plain and commodious edifice, rebuilt in 1750. The places of worship for dissenters are a Roman Catholic chapel, and meeting houses for Presbyterians; Unitarians, Baptists, Methodists, and Quakers.

The *Town and County Gaol and Bridewell* form an edifice beautifully situated near the castle. It has a good freestone front, with an arched gateway, containing a bust of Howard by Bacon. It is a spacious, airy, and commodious building.

The *Market-house*, remarkable for its size and magnificence, was erected in 1595. In the principal front, which is towards the west, the portal is decorated with two Elizabeth's arms in high relief; and on each side of it is an open arcade of three large circular arches supported by columns. Large open arches likewise decorate the north and south sides, and over one of them is a statue of Richard, Duke of York. Close to this building is a conduit, which supplies with water a great part of the town.

The Market Cross was a massy building of brick and stone, having a reservoir over it. It was taken down in 1819. The reservoir was removed farther back, and a handsome new market house built by subscription.

The *Theatre* is supposed to be part of the palace which formerly belonged to the later princes of Powis. It is fitted up with tolerable neatness.

The *two bridges* over the Severn are called the Welsh Bridge and the English or East Bridge. The former consists of 5 handsome arches, and is 226 feet long, 20 feet high, and 30 feet broad. A quay faced with stone, and with warehouses, adjoins to the bridge. The English Bridge, built of fine freestone, consists of 7 semicircular arches. It is 400 feet long. The middle arch is 60 feet span and 40 high, and the rest 35 feet span and 20 feet high. The width between the balustrades is 25 feet, and the ornaments are light and graceful.

The principal charitable establishments are a small hospital dedicated to St. Giles, Millington's Hospital, several alms houses, an infirmary, a house of industry, a free grammar school, and several charity schools.

The *Infirmary*, opened in 1747, is a plain but respectable brick building, with a stone portico in front and stone corners. It is in a healthy situation, and its internal arrangements are on the most approved footing. It is supported by voluntary subscription. The House of Industry, opened in 1784, maintains about 275 persons. The school-house and the free grammar school is a large and lofty building, forming two sides of a square court. In consequence of this institution having declined, an act of Parliament was passed in 1798, vesting its management in the Bishop of Lichfield and Coventry as visiters, and in 13 trustees, of whom the mayor is one. These trustees elect two schoolmasters, one of whom is superior to the other. The other public schools are Bowdler's Charity, founded in 1724, for educating and clothing poor children; Allart's Charity School, founded in 1798; and a Subscription Charity School, founded in 1708, for instructing poor children.

A few inconsiderable remains of the Abbey of St. Peter and St. Paul still exist in the suburb called the Abbey Foregate. The ground which it occupied is in a great measure converted into a garden. Among the remains is a small octagonal stone building generally called the Stone Pulpit, which is overhung with ivy, and much admired. The abbey was a spacious and magnificent building. The only existing part of it is the nave, which is now used as a Romish church under the name of the Holy Cross. The beauty of its original structure may still be traced in many parts. Among other ancient private structures in the town is one called the Council House, which was once the residence of the Court of the Marches of Wales.

Shrewsbury is governed by a mayor, a warden, steward, town clerk, an alderman, 48 assistants or common councilmen, and other officers. There are in the town 16 chartered companies. Shrewsbury sends to Parliament 2 members, who are elected by the inhabiting burgesses.

The principal manufactures carried on in the town are two of linen yarn, an extensive iron foundry, and a porter brewery. Shrewsbury carries on a considerable trade principally with Wales; and about 20 vessels are employed on the Severn between Gloucester, Shrewsbury, and Bristol. Flannels were formerly the staple articles, and Welsh webs, which were a coarse kind of woollen cloth made in Montgomeryshire. They were dressed in Shrewsbury for importation to Holland, Germany, North and South America, and the West Indies. These webs are now bought up in the counties where they are made.

At the entrance to Shrewsbury by the London road there has been erected a magnificent column of freestone, with appropriate inscriptions, to commemorate the gallant achievements of Lord Hill, a native of the county. It was completed in 1816 at the expense of above £6000, which was defrayed by subscriptions in the town and county. Population in 1821, 21,695. See *the Beauties of England and Wales*, vol. xiii, and *Some Account of the Ancient and Present State of Shrewsbury*, 1808, and Philip's *History and Antiquities of Shrewsbury*.

SHROPSHIRE, or SALOP, one of the midland counties of England, is bounded on the south by the counties of Worcester and Hereford, on the east by that of Stafford, on the north by Cheshire, a detached part of Flintshire and Derbyshire, and on the west by Derbyshire, Radnorshire, and Montgomeryshire. Its shape approaches to that of an oval, and it is about 44 miles long from north to south, 28 broad from east to west, and 134 in circumference. It contains 1341 square miles, or 854,240 statute acres, and about 140 inhabitants to each square mile. This county is divided into fifteen hundreds, which are again subdivided into 229 parishes. It contains 262 churches, of which there are 114 in the diocese of Lichfield and Coventry, 127 in that of Hereford, 12 in that of St. Asaph, 3 in that of Worcester, and 6 in the peculiar jurisdiction of Bridgenorth. Shropshire contains 16 market towns, and sends 12 members to Parliament.

This county presents a very diversified aspect; on the eastern side the surface is partly undulating and tolerably well wooded, exhibiting in many places fertile and well cultivated districts, enclosed with good hedges. On the western side it exhibits the bold and lofty character of Welsh scenery.

The principal mountain elevations are the Brown Clee Hill, 1805 feet high, and the Titterston Clee Hill in the southern part of the county, both of which are surrounded with much picturesque scenery. The Wrekin is a singular insulated mountain of a sugar loaf form, rising from a plain to the height of 1324 feet. From it there proceeds northward, across the Severn, a range of trap mountains, consisting of the hills of Acton, Burnes, Frodesley, the Lawley, Caer Caradoc, and Hope Bowdler hill. These mountains are separated by a valley from a singular mass of hills, called the Lionmynd, 1674 feet high. A high rocky track rises between the road from Shrewsbury to Bishop's Castle and the vale of Montgomery, and in the most elevated peak of it, called the Stiperstones, are situated the lead mines.

The principal river in Shropshire is the Severn, which runs through the county from north-west to south-east, and nearly divides it into two parts. It enters the county from Montgomeryshire at its confluence with the Vyrnwy, and running eastward to Shrewsbury it bends towards the south, and passing by Wroxeter, Madely, and Bridgenorth, it leaves the county near Bewdley on the borders of Staffordshire and Worcestershire. It flows about 70 miles within the county, in every part of which it is navigable at all seasons except the height of summer, for barges, trams, wherries, and boats. In this navigation men are employed instead of horses to draw the barges against the stream. Salmon, pike, flounders, grayling, and eels, are found in the Severn while it flows through Shropshire. The principal streams tributary to the Severn are the Camlet, the Vyrnwy, the Pery, the Meole brook or Rea, the Tern, the Cund brook, the Warf, the Mor brook, the Bore brook, and Dowles brook. The other rivers in the county are the Terne, the Shell-brook, the Elf-brook, the Weaver, the Clun, the Morles, the Ony, and the Corve.

The lakes in Shropshire, though numerous, are not of great extent. The largest is that of Ellesmere, which contains about 116 acres; that of Marton Pool contains 45 acres; and at Shrawardine is a fine lake of 40 acres. The other lakes are Fennymere, Lyncly's-pool, and Ancot. There are many canals and several iron bridges in this county, but we have already given a full account of them in our articles BRIDGE, and NAVIGATION INLAND.

The climate of Shropshire varies with the elevation. On the eastern side, where the land is warm and flat, harvest often begins a fortnight earlier than in the middle of the county, and hay and grain are both gathered earlier there than in the western side. The easterly winds prevail in spring, and the westerly ones in autumn. The former are the most regular, while the latter blow for five or six months strong and frequent, the other for nearly the same length of time with less violence. The cold of winter is felt very intensely on the hills in the western part of the county.

The soil in the eastern side of the county is generally of a sandy nature. For the most part it is more tenacious, and there is often a stiff but rich clay in the bottom of the wider vallies. In the most western parts the soil is very shallow, resting principally upon rocks of different kinds, and is more or less used for pasturing sheep than for raising grain. The rapid progress of improvement in enclosing and draining has greatly diminished the moor lands. A very great part of the soil of the county rests upon a limestone subsoil.

The operations of agriculture are better conducted in Shropshire than in many other counties in England. The farms are commonly large. They are, in some instances, held on leases for life—in others, on leases of seven, ten, and twenty-one years, and in many cases from year to year. The crops commonly cultivated are wheat, barley, oats, pease, turnips, and potatoes. Hops, hemp, flax, and cabbages are raised only in small quantities. The growth of hay, and the improvement of pasture land, have been more overlooked than any other branch of rural economy. On the banks of the Severn, however, and on the margin of several of the lesser streams, there are many excellent tracts of meadow land, which are enriched solely by the deposits of the rivers when in flood. Almost all the cultivated lands in Shropshire are enclosed. The principal commons that remain are that of Morf, near Bridgenorth, about five miles long, and three broad, and the high lands between Church Stretton and Bishop's Castle, and from Clun to the borders of Radnorshire. There are several large mosses in the county. The principal herd of sheep is the Southdowns, but there are many of the New Leicesters, and several of the fine-woolled Welsh sheep in the hilly districts. In the neighbourhood of the Wrekin of Bridgenorth and of Clun, the wool is considered to be equal in quality to that of Leicester.

Shropshire has been long distinguished for its mineral productions, and the trades and manufactures to which these have been subservient. The principal of these are coal, iron, lead, limestone, freestone, petroleum, and pipe-clay. Good *coal* is found in abundance in different parts of the county. The most important coal field, however, occupies a district near Colebrookdale, about eight miles long and two broad. The coal is here found at various depths, alternately with ironstone, sandstone, and other rocks. The strata slope to the east in Madeley parish, and to the north and north-east near Wellington and Lilleshall. A long broad range of sandstone bounds the coal district on the east, commencing north of Shiffnall, and following the line of the Severn till it leaves the county. On the south and west it is bounded by limestone, and the basalt of the Wrekin. The southern part of the coal district, and indeed nearly the whole of it, is considerably elevated above the plain of Shropshire, so that at one part the height is 500 feet above the Severn. Near the north-west boundary of the county is another bed of coal, which is wrought to a considerable extent, and is employed in the lime works of Chirk and Llanymyneck. On the west this coal field is bounded by, and lies above an irregular bed of limestone, which in some places scarcely appears above the surface, and in others rises to a height of 500 feet. On the east the coal field is bounded by a ridge of sandstone, stretching from Ellesmere along the Perry, crossing the Severn, and ending at Bicton and Onslow. Another coal district in the south of the county, particularly on the Brown Clee and Titterson Clee Hills, consists of various detached beds or hollows, in which the strata has the form of a cup. In the first of these hills the strata are so thin that they are wrought only by poor colliers: but in Titterson the chief stratum is six feet thick, and there are here six coal fields, the principal of which is the Cornbrook, the Newbury, and the Hillwork coal fields. The first is a mile long, and half a mile broad.

The *ironstone* occurs in the neighbourhood of the coal, and frequently close to it. It is not rich, but being found along with coal and lime, the fuel and the flux, it has rendered Colebrookdale the seat of the most extensive iron works in the kingdom.

Lead is procured in considerable quantities from various parts of the Stiperstones, but particularly from the Hope and Snailbeach mines. Its matrix is crystallized quartz, sulphate and carbonate of barytes, and carbonate of lime. It occurs in the form of sulphuret of lead, and the carbonate. It is reduced at Minsterley and other places near the mines, and is sent by land to Shrewsbury, where it is shipped for Bristol in the Severn barges.

Limestone is quarried in various places, but particularly at Lilleshall, Porth-y-wain, and Llanymynech, and likewise in the parishes of Cardiston and Alderbury. The limestone in the south forms the northern extremity of a long range, which joins Wenlock, in a south-west direction, to Hope Bowdler Hill, near Church Stretton, and thence in a southerly direction to the neighbourhood of Ludlow. In many parts of the irregular band of limestone, mentioned in the paragraphs on coal, especially near Oswestry, the limestone is in the state of perfect marble, and there have been found in it small quantities both of lead and copper.

The *sandstone*, which is found so extensively in Shropshire, is chiefly red; but in some places it is found white, particularly at Grinshill, where it has been quarried to a great extent, for the churches, bridges, and other public edifices in Shrewsbury.

In the coal field of Colebrookdale there is a spring of petroleum, which formerly yielded a great quantity of this mineral tar. It also exudes from a red sandstone at Pitchford, about seven miles south-east of Shrewsbury. From this rock has been extracted an oil known by the name of Betton's British oil. A quartz and clay have been found in the lordship of Cadington, the first of which is said to be superior to that imported from Caermarthenshire for the potteries of Staffordshire. Copper and blende, which yields calamine, is also found in the Stipertones, but neither of them have been wrought with any success. There is a brine spring in the same district with the Pitchford rock.

The principal seat of the manufactures of Shropshire is Colebrookdale, "which," says Authur Young, "is a winding glen between two enormous hills, which break into various forms, being all thickly covered, and forming most beautiful sheets of hanging woods. The noise of the forges, mills, furnaces, &c. with all their vast machinery; the flames bursting from the furnaces, with the burning coal and smoke of the limekilns, are altogether horribly sublime." Iron works exist also at Ketley and Oakengates. Besides the process of separating the iron from its ore, and bringing it into the state of bar and pig iron, iron goods of various kinds are manufactured. All the iron bridges in the county, the iron work of Pontcysylte aqueduct, which is all of iron, except the piers, and many of the iron bridges erected in other parts of the kingdom, have been made in Shropshire. At Coalport, coloured china of all kinds, and likewise Queen's or Wedgewood ware, is manufactured. At Caughley there is an excellent china manufacture; and at Brosely, garden-pots, tobacco, paper, and coarse articles of earthen-ware are made. Considerable potteries have been established in the district of Colebrookdale, particularly one for ironstone china, which has greatly lowered the price of that article. A work is also carried on here for obtaining coal tar from the condensed smoke of the coal. Cotton manufactories have been established at Coleham and other places, which rival the largest in Lancashire. Many branches of the linen trade have been carried on in the northern part of the county, and some of the coarser kinds of woollens have been manufactured in different districts, and several mills have been established for dyeing woollen cloths.

The trade of Shropshire has been greatly benefited by the canals which have been carried on to a great extent, and of which a very minute account will be found in our article Navigation Inland. The navigation of the Severn yet requires much improvement. Pathways have for some time been constructing along its banks, in order that horses may be employed in place of men in towing the barges up the river.

At the time of the Roman invasion, during the reign of Claudius, Shropshire was inhabited by the Ordovices and Cornavii. It was afterwards part of the province of Flavia Cæsariensis. The principal Roman stations were Uriconium, now Wroxeter, Mediolanum, near Drayton, and Rutunium, near Wer. Watling Street enters the county on the east between Cracklay bank and Weston, and passes through it in a bending line to Leintwardine, in Herefordshire. Some of the principal remains of ancient architecture are Haugmond Abbey; the walls of Wroxeter, which are of Roman and British construction; the abbey of Buildwas; the monastery of Wenlock; Ludlow Castle, the residence of the Sidneys and the place where some of Milton's works were composed; Wannington Castle; Lilleshall Abbey, remarkable for some highly ornamented Norman arches; and Roscabel House, with the oak which sheltered Charles II. after the battle of Worcester. The most remarkable encampments are the Roman camp, called the Walls at Quatford, and those of Buryditches, Purslow, Basford Gate, and Hawkstone.

The estates are here of various sizes. A few noblemen and gentlemen possess estates from 10,000 to 25,000 acres. The number of freeholders entitled to vote for the two members sent from the county amount to 5000, and the total rental, including tythes, is about £900,000.

The following are the principal residences in the county. Wolcat Hall, Earl Powis; Hardwicke, Lord Hill; Rosshall and Welley Park, Lord Forrester; Apiey Park, Thomas Whitmore, M. P.; Dudmaston, William Whitmore, M. P.; Pitchford, Hon. Mr. Jenkinson, M. P.; Hodnett, Reginald Heber, M. P.; Hawkstone, Sir R. Hill, Bart. M. P.; Kinlett Hall, W. C. Childe, Esq. M. P.; Stanley Hall, Sir T. Tyrwhitt Jones, Bart.; Allingham, Lord Berwick; Manor House, Sir G. Jernyingham, Bart.; Pradoe, Hon. T. Kenyon; Pentrapent Hall, Hon. F. West; Orlaton Hall, W. Cludd, Esq.; Downton Castle, R. Payne Knight, Esq.; Oakley Park, Hon. Robert Clive; Plowden Hall, Edward Plowden, Esq.; Audlem, Lady Cotton.

The following is the population of the county and principal towns in 1821:

	Members of Parliament.		Population.
Shropshire,	two		206,153
		Males	102,056
		Females,	104,079
		Families	41,636
		Do. in trade,	17,485
		Do. in agriculture,	18,414
		Inhabited houses,	38,663
Shrewsbury,	two		21,695
Wenlock	two		17,265
Wellington,			8,390
Hales Owen,			8,187
Ellismore,			6,056
Ludlow,	two		4,820
Bridgenorth,	two		4,365
Oswestry,			3,910
Newport,			2,313
Bishop's Castle,	two		1,880

See the *Beauties of England and Wales*, vol. xiii. Archdeacon Plymley's *General View of the Agriculture of Shropshire*, 1803. See also our articles BRIDGE, NAVIGATION INLAND, and RAILWAY. See also ELLESMERE, and BRIDGENORTH.

SHRUBS, See HORTICULTURE.

SHUS, See KHUZISTAN.

SHUSTER, the principal district of KHUZISTAN, already described in that article.

SHUSTER, a city of Persia, and capital of the province of Khuzistan. It is situated at the foot of the Backtiari range of mountains, and on an eminence which commands a view of the rapid course of the Karoon, which is here crossed by a bridge, of an arch 80 feet high. The Persians are said to throw themselves with impunity from the summit of this bridge into the river. The river defends the town on the west, and on the east a decayed old wall performs this function: the streets are narrow and dirty, but the houses are principally built of stone, and many of them are good. The castle is situated on a small hill to the west of the town. It is defended on two sides by a ditch almost filled up with sand, and on the other two sides by a branch of the Karoon. It has one gateway, which was formerly entered by a drawbridge. The hill on which it stands is almost wholly excavated, and formed into subterraneous aqueducts, through which the water still continues to flow. In the vicinity of the castle, is the dyke which Sapor built across the Karoon, in order to irrigate the adjacent lands.

It consists of hewn stone, bound together with clamps of iron, and is about 20 feet broad, and 400 yards long, with two small arches in the middle. Mahomet Ali Meerza, governor of Kermanshaw, has lately rebuilt it, with great advantage to the country. The artificial canal of water, obtained by means of the dyke, falls, after a long winding course, into the Dezphoul, near Bundekeel. There is near the canal, a bridge built of hewn stone, consisting of 32 arches, of which 28 are entire. There is in this city a considerable manufacture of woollen stuffs, which are sent to Bassirah, and there exchanged for Indian goods. This city is resorted to by invalids for its salubrity. In summer, the heats are so excessive from 9 A. M. till 9 P. M. that the inhabitants spend the day in subterraneous apartments, and pass the night on the flat roofs of their houses. The population, which amounts to 15,000, is composed of Arabians and Persians. East Long. 48° 59′ North Lat. 32°. See Macdonald Kinneir's *Memoir of the Persian Empire*, p. 97.

SHWANPAN is the name of a Chinese instrument, for assisting them in their computations. It is a variety of the Abacus (See ABACUS.) and consists of several series of beads strung on brass wires, and extended from the top to the bottom of the instrument, and divided in the middle by a cross piece going from one side to the other. In the upper row, each string has two beads, each of which counts five, and in the lower row, each string has five beads, the *first* being reckoned 1, the *second* 10, and the *third* 100, &c. The Chinese Shwanpan differs from that of the Roman, in having strings and beads in place of pins and sliding grooves. Instead of four pins for units as the Roman had, the Chinese have five beads, so that the Chinese instrument seems intended for the decimal, whereas that of the Roman was suited to the duodecimal scale. Mr. Smethurst has described a new Shwanpan, formed "on the plan of our nine numbers, that in no case falls short of the Chinese Shwanpan, but in many excels it." See *Phil. Trans.* 1749, vol. xlvi. p. 2. See also some observations by Dr. Hooke on the Shwanpan in the *Phil. Trans.* 1686, vol. xvi. p. 63.

SIAM, a kingdom of Asia, situated beyond the Ganges, and bounded on the west by the Birman Empire, on the south by the Gulf of Siam, on the east by Cambodia and Cochin China, and on the north by portions of China and Tartary. This kingdom consists properly of the wide valley of the Menam, (a large river which flows from Thibet,) lying between two ranges of mountains; but it comprehends also an extensive territory, including almost the whole peninsula of Malacca, and comprehending the following states, beginning from the North at Bankok:*

Rachpuri,	Ligor,
Puchpuri,	Dalonny,
Chimpohim,	Singoora,
Chaiya,	Kingdom of Queda,
Salang,	Kingdom of Perah.

The province of Tenasserim, lying to the east of the three first of the above states, has been wrested from the Siamese. As this territory has been already described under the article Malacca, we shall at present consider Siam in reference only to the valley of the Menam, and the province of Chantibond, which recently was joined to Siam. A great part of this kingdom consists of mountains, at the base of which are extensive and unproductive swamps and jungles. The agriculture of Siam is limited to the production of rice and sugar, which are raised on the grounds bordering on the river Menam; and as these are inundated during part of the year, the crops are abundant; though what is raised on dry soil is preferred.

The sugar cane has been introduced into Siam within the last *twenty* years. The culture of it is managed solely by the Chinese, and it is supposed that it may be carried to an almost unlimited extent. The annual produce in 1821, was about 30,000 peculs, or nearly 1788 tons. The other productions of Siam are pepper, the annual produce of which, in Chantibond, is 20,000 peculs, 133 lbs. each, benzoin, tea, ivory, aguila wood, rhinoceros' horns, hides of cows, buffalos, and deer, gamboge, cardamoms, &c. Most of these articles are obtained most abundantly from Chantibond, where precious stones and gold, &c. are also found.

The principal fruits are the durio, the mangosteen, pine apple, tamarind, banana, areka, betel, cocoa nut, from the last of which they obtain milk, oil, and pitch which makes good torches.

Among the animals of Siam, the elephant holds the principal place. The hunting of them is a royal monopoly. The finest are kept for the king's use, and the rest exported. A white elephant is reckoned beyond all value; and in the time of the French embassy, there was one which was served by 100 attendants. It was lodged in a gilded stable, and drank out of a trough of massy gold. In 1822, there were five of these in the king's possession. These animals are, in short, albinos, and their eye was natural and sound, though the iris was pure white. In one or two of them, the colour was strictly white; and in all of them the iris was of that colour, and the margin of the eyelids; but in the rest, the colour had a cast of pink in it. In none did the colour and texture of the skin appear entirely healthy. They were small, but in excellent condition; and one of them, which was handsome, was treated with great attention. Fresh cut grass was placed in abundance before them, and they were fed with sliced sugar cane, and branches of plantains. They stood on a small boarded platform kept clean; and a white cloth was spread before them. Mr. Finlayson describes another elephant covered with black spots the size of a pea, on a white base. The discoverer of a white elephant is rewarded with a crown of silver, and with a grant of land equal in extent to the space of country over which the elephant's cry may be heard. He and his family are freed from all sorts of servitude, and their land from taxation, to the third generation. The other animals are tigers, rhinoceroses, leopards, white monkeys, tortoises, hedge-hogs. Domestic animals are few, and little esteemed, excepting the hogs, the flesh of which is superior to that of Europe.

Commerce is in a very singular state in Siam. The king and his ministers are the sole merchants, holding the monopoly of all articles of importance. Great encouragement is given to the Chinese traders, who have sown the seeds of commercial enterprise in Siam. All the Siamese are totally ignorant of maritime science; the king employs native Christians, Arabs, and other Mahommedans, to navigate his vessels. He, nevertheless, sends every year to China ten or twelve junks, of moderate size, laden with sugar, pepper, japan, and iron wood. He is, however, anxious to establish commercial relations with Europe; but the regulations are so illiberal, as to disgust the fair trader. The introduction of opium has been long, and is still strictly prohibited.

The principal towns in Siam are Bankok, the capital or the residence of the king, Siam, Juthea, or Odia, formerly the capital, and situated on the Menam, Loub and Porselone on the Menan, and several others along the west shores of the Gulf of Siam. Bankok contains many splendid temples, including the Prachadi, of a spiral form, probably the sepulchral monument of Buddha. The palace is situated on an island two or three miles long, and it and the whole island is surrounded by high walls, and bastions, and numerous gates. The persons attached to the court reside here in wretched huts, made of palm leaves. The greater part of the space which the wall encloses, consists of waste ground, swamps, and fruit gardens. The city, which is continuous with the palace, extends on both sides of the river Menam, to the distance of three or four miles. It is built entirely of wood; the palaces, temples, &c. having brick or mud walls. The houses rarely extend more than one or two miles from the river, *and by far the greater number of them float on bamboo rafts*, secured close to the bank. The houses not thus floated, are built on posts driven into the mud. Every house has a boat. The principal shops are in the floating houses. The Chinese appear to exceed the natives in number. The floating houses consist of one floor, and have a very neat appearance, being thatched with palm leaves, and sometimes with tiles. They are divided into several apartments, the centre

* This information is taken from a sketch of the Siamese States between Bankok and Queda, surveyed in 1825, and sent to us by a correspondent in India. According to Hanel, Siam and Malacca contain about 143,000 square miles.

one of which is allotted for the household goods. The principal traders are the tinsmith, blacksmith, and currier. Tin vessels are made to a great extent. The preparation of leather for covering mattresses and pillows, and for exportation to China, is very extensive. The skins chiefly used are those of the deer, ox, and buffalo. The skins of leopards and tigers, with the fur on, are exported to China. There are one or two manufactories of shallow cast iron pots, conducted by Chinese. In 1827, two dreadful fires destroyed above 1500 houses in Bankok.

Juthea, the old capital, stands on the Menam, about 40 miles above Bankok. It is surrounded with a turreted brick wall. The town is intersected with several large canals; the streets run along them, that the ships may land their goods at the principal houses. Most of the streets are narrow and dirty. The larger bridges over the canal are of stone, and the smaller of wood. There are three palaces in the city, the chief of which is of Chinese architecture. The suburbs are numerous; some of them consist of floating houses, and of houses fixed in the water on posts, as at Bankok.

The government of Siam is perfectly despotic. In cases where the interests of the king and his minions are not immediately concerned, the laws are often equitable and severely just; but the judges are corrupt.

The revenue of Siam is considerable. The land-tax is paid chiefly in kind. The privilege of fishing and distilling arrack produces a considerable sum. The most important fruit trees are taxed, and the tax is said to yield 7000 catties of silver. Gambling houses are also taxed.

The inhabitants seem to be of Mongol descent. Their average height is five feet three inches. Their complexion is yellow. Their face is very broad and flat, their hair is always black, and they have a tendency to obesity. They have the frame without the energy of London porters.

The poorest of the Siamese are, after death thrown into the river. Those a little above them are burnt, and their partially consumed bones left to bleach on the plain. Children, before the age of dentition, and women who have died pregnant, are interred in a superficial grave, till after the lapse of a few months the remains are taken up and burnt.

With these exceptions, the practice of cremation extends to all ranks. In many instances previous to cremation, the muscular and soft parts of the body are cut into small pieces and thrown to dogs, vultures, and other carnivorous animals. Among the higher classes, the body is embalmed previous to cremation, but this art is very little known.

The music of the Siamese is soft and lively. They are very fond of music, and have arrived at great proficiency in the art. Their vocal music is plaintive and melancholy.

The history of Siam, beyond what is given in our account of the Birman empire, is scarcely worth noticing. The late king, who ascended the throne in 1782, has been constantly at war with the Birman empire, and it was the boast of his reign that he has lost nothing in the contest.*

The population of Siam is not known. That of the province of Chantibond is stated by Mr. Finlayson to be nearly one million. As very little is known of the modern state of Siam, we have not occupied our pages with any of the antiquated information which is generally detailed. Those, however, who wish such information, may consult La Loubere's *Description du Royaume de Siam*, Amst. 1719. Turpin's *Histoire civile et naturelle du Royaume de Siam*, Paris, 1771. This work was compiled from the MSS. of the bishop of Tavolia, apostolical vicar of Siam, and other Missionaries. *Bemerkungen uber Siam*, in the *Connaiss ance de la literature des pays*, 1786, cap. 12. The most recent information respecting Siam will be found in Finlayson's *Account of the Mission to Siam and Hue* in 1821-2, Lond. 1826. See also Birman Empire.

SIAMPA, or Tsiampa, or Chiampa, or *Binh-tuam*, is a state included in the empire of Tonkin. It is inclosed in Cochin China, which bounds it on the north and south, the Chinese sea bounds it on the east, and Camboge on the west. It is a small mountainous country, which may be crossed in three days. The eastern part is a desert composed of mountains, some of which extend their roots to the sea. They are so steep that a horse cannot ascend them. The road from lower to central Cochin China passes across these mountains, though there is no water fit for drinking in the whole of this route.

The middle part of Siampa is inhabited and cultivated, and western Siampa is a mountainous country where there are some wandering savages, many of whom are not clothed.

The inhabitants of Siampa, particularly the mountaineers, are unknown to their neighbours the Cochin Chinese. They are not known to have any religious belief. They are circumcised, but it is uncertain whether this operation is a precaution, or a medical measure, or an act of religion.

No European is known to have penetrated their country.

The villages are said to be very agreeable, and the mountains abound with wild buffalos.

There are only very small villages in Siampa. The population is reckoned at from 6 to 700,000. See *Exposé Statistique du Tonkin, de la Cochin China, du Camboge du Tsiampa*, &c. from M. M——n, Londres, 1811.

SIBERIA, an extensive territory in Asia, which includes the whole of the northern frontiers of that quarter of the globe. As a part of the Russian empire it has received the name of Asiatic Russia. Siberia is a flat track of country, declining gradually to the frozen ocean, by which it is surrounded on the north, rising gradually towards the south till it joins a great chain of mountains distinguished by the name of the Altai mountains, and the mountains of Sagansk and Yablonay, which separate Russia from independent Tartary, and the territories subject to China. On the east it is bounded by the Eastern Ocean, and

* He was succeeded within these two or three years by Prince Prom Chit, his natural son, who declared when he ascended the throne, that he would no longer be a king merchant, but would allow a general free trade. A commercial treaty was concluded in 1826 by a mission to Siam, between Great Britain and that country; and many points arranged which must facilitate the operations, and protect the person of the British trader.

on the west by the great chain of the Uralian mountains, which divide it from Russia in Europe, and from the provinces of Orenbourg and Astrakan. Siberia extends from the 57th to the 75th degree of North Lat. and from the 60th to the 190th degree of East Longitude. It varies from 1200 to 2000 miles in breadth from north to south, and is about 4500 miles long from east to west.

Siberia is divided into three provinces, which form the 49th, 50th, and 51st, of the Russian Empire. These provinces have the following extent and population.

	Population in 1810.	Extent in square miles.	Inhabitants for each square mile.
Tobolsk,	427,066 }	85,387	8⅔
Tomsk,	293,967 }		
Irkutsk,	376,720	127,888	3

In our article Irkutsk, we have already given a full account of that province, which forms the whole of the eastern part of Siberia. And in our articles Tobolsk and Tomsk, we shall describe the western part of this territory.

In our article Russia, will be found many interesting details of a general nature respecting the territory of Siberia. See also our articles Aleutian Islands, Altai Mountains, Asia, Bhering's Islands, Kamtschatka, Kurile Islands. See also the works referred to under our article Russia.

SIBYLS, from σιου or Θεου *of God*, and βουλη *counsel*, is the name given to certain sages who were supposed to possess prophetic powers, and who uttered oracular responses. They were supposed by some to be four in number, viz.—

The Erythræn Sibyl,
The Egyptian Sibyl,
The Sibyl of Samos,
The Sibyl of Sardis, or the Delphian.

Capella enumerates only two, the Phrygian and the Erythræn; Solinus makes three, viz. the Cumean, the Delphic, and the Erythræn. Varro raises them to ten, while more modern writers suppose that there was only one who uttered her oracles in different places.

The Sibylline oracles, which were a collection of the responses of the Sibyls in nine books, were written in verse, and were offered to Tarquin the elder, according to Varro, by an old woman for 300 pieces of gold. This sum being rejected, she threw three books into the fire, and asked the same sum for the remaining six. This demand being refused also, she burnt other three, and asked the same sum for the remaining three. Tarquin now began to fear that she would destroy the last three, and gave her the sum required. These books, which were in the custody of two patrician priests, were burnt in the fire which destroyed the capital in the year 83 B. C. For farther information, as to these and other books to which the name of Sibylline has been applied, see Hyde, *De Relig. Vet. Pers.*; Prideaux's *Connexions, &c.* vol. iv. p. 185; and Lardner's *Credibility of the Gospel History*, vol. iv.

SICILY, the largest island in the Mediterranean sea, situated close to the southern extremity of Italy, from which it is separated on the west by the straits of Messina. In consequence of its approximation to a triangular form, it was called *Trinacria*, or *Triniquetra*, by the ancients. Its length from east to west is 180 miles; its greatest breadth about 130, and its extent, including the small islands upon its coast, is nearly 12,533 square miles.

Sicily was formerly divided into three parts:

1. The Val di Mazzara, or western part.
2. The Val di Demona, or north-eastern part; and
3. The Val di Noto, or southern part.

But since the year 1815, when the government of Murat was overthrown, it has been divided into seven intendancies, the population of which and of the principal towns are as follows:

Intendancies.	Population in 1817.	Towns.	Population of the chief towns.
Palermo	405,231	Palermo	180,000
Messina	236,784	Messina	44,650
Catania	289,496	Catania	45,081
Siragossa	192,710	Siragossa	13,850
Caltanisetta	155,225	Caltanisetta	15,627
Girgente	288,877	Girgente	14,882
Trapani	145,712	Trapani	24,330
Total	1713,945		

The following table contains the population of the other principal towns in Sicily, in the order of their magnitudes:

Marsala	25,000
Modica	24,000
Ragusa	20,000
Termini	20,000
Noto	16,000
Syracuse	14,000
Nicosia	13,000
Salemi	12,000
Alcamo	12,000
Agosta	12,000
Naro	12,000
Corleone	12,000
Licata	12,000
Castel Vetrano	12,000
Randuzzo	12,000
Sciacca	11,000
Scicli	11,000
Vittoria	11,000
Mazzara	10,000
Castro Giovanni	10,000
Cefalu	10,000

The general aspect of Sicily is that of a highly mountainous country, variegated with numerous vallies. The principal chain of mountains extends from east to west, and has been regarded as a continuation of the Apennines. Other lesser ranges branch off from the main range from north to south; and there are some insulated mountains, of which Ætna is the most remarkable, and of which we have already given a very full and elaborate description in our article Ætna. The north coast of Italy presents a very level surface for nearly 100 miles to the east of Trapani, and also near the gulf of Castello Mare on the opposite side of the island. The plains of Melazzo and Catania, on the north-east of the island are the most extensive, and next to them those of Terra Nova in the south, and of Syracuse in the south-west. In the west of the island there are very extensive districts uninhabited and destitute of cultivation.

The principal rivers in Sicily are the Fiume Grande, the Giaretta, anciently the *Simoethus*, and the Salso. These rivers, and the other smaller ones that water the island have but a very short course, and descend very rapidly from the mountains. As there are almost no carriage roads except in the vicinity of Palermo, there are of course very few bridges over the rivers.

The principal lakes in Sicily are the Biviere and the Pergusa. The Biviere, about eight miles south of Catania, has, in the winter season, a circumference of about 20 English miles, while in dry weather it is reduced to very small dimension, leaving an extensive swamp, which is most injurious to health.

The climate of Sicily is, generally speaking, an agreeable one. In summer the weather is very hot; the thermometer at Palermo varying from 73½° to 80½° in June and July. When the *sirocco* or south wind blows, which happens during a few days of July and August, the thermometer rises suddenly to 112°. Though the summer heat is often alleviated by fresh sea breezes, yet March is the only month in which any chilling winds are felt; and the shade is found refreshing even in the beginning of January. The spring is the finest season of the year. Snow is never seen excepting on the lofty mountains, and in the low grounds are found the productions of the tropical countries, such as the banana, the aloe, the sugar cane, &c. Against these advantages, we have to balance the insecurity of particular districts, the season of the sirocco, and the exposure of the island to frequent and desolating earthquakes.

Sicily was laid waste by earthquakes in the years 1638, 1693, 1726, 1783, 1805, and 1818-19; but the most tremendous effects were produced by that which took place in March 1823*. On the sea coast east of Palermo, the shock was immense. At Altavilla, the bridge was shaken. At Trabia, the castle was destroyed. At Godiano, the cathedral and some houses fell, and enormous masses were loosened, and fell from Bisambra, a neighbouring mountain. At Termini, the shocks exceeded all that had happened in the memory of its oldest inhabitants. The warm springs then became turbid and increased in quantity and warmth. In Sarcari most of the houses were rendered uninhabitable. To the west of Palermo, the earthquake had little power; but as it advanced to the east, its effects were very injurious. At Cefalu, the sea made a violent and sudden rush to the shore, carrying with it a large ship laden with oil, and when the wave retired she was left dry; but a second wave returning with immense force, dashed the ship to pieces. Boats which were approaching the shore, were borne rapidly forward to the land; but they were carried as rapidly back, at the return of the sea. Some damage was done at Messina. At Catania, it was felt so slightly, that the people went to the theatre that same evening. It was slightly felt at Syracuse, scarcely at all towards Cape Passaro, and no bad effects were produced in the southern part of the island.

Sicily has long been celebrated for the fertility of its soil. Excepting in the vicinity of Ætna, the soil is calcareous loamy mould of considerable depth. The copious dews of June supply the want of rain, and the melted snows which fill the rivulets with water, afford excellent means of irrigation. Although it is not cultivated at present, as when Sicily was deemed the granary of Rome, yet the crops of wheat are so abundant, as not only to supply the inhabitants, but to leave a considerable surplus for exportation. It was only, however, in 1819, that the export of corn was declared to be free. Mr. Brydone assures us, that one good crop of wheat is sufficient to feed the island for seven years. Large quantities of barley and pulse grow on the island; and maize, flax, hemp, aloes, saffron, wine and cotton, are among its productions. Canary bird seed, which is almost peculiar to this island, is exported in large quantities. Potatoes were introduced in the eighteenth century; and in consequence of the goodness of the pasturage, milk, cheese, and butter are obtained in considerable quantities.†

Silk is considered the second source of riches in Sicily. The management of the silk worms, and the art of manufacturing the silk, were introduced by Roger, king of Sicily: a quantity of silk, equal in value to a million of ducats, or £187,500 sterling, was annually exported, but this has greatly declined. Palermo and Messina are the principal seats of the manufacture. Palermo employed 900 looms, Messina 1200, and Catania rather more. Palermo exports little. A variety of silken fabrics, made at Messina, went to the Levant. Cotton, linen, and woollen goods are likewise manufactured in these three towns, and also bits, cutlery, harness, carriages, and household furniture. Large quantities of oil were exported from ports in the north of the island, and also wines and brandy. The fisheries are productive, and great quantities of herring, anchovies, and sardines, are sold and exported.

Sicily has not yet attained that commercial importance to which it is entitled from the excellence of its harbours, and the safety of its shores, for navigation. Its inland communications are fettered by the want of roads; and the want of banks, insurance offices, together with a bad system of quarantine laws, retard the progress of its commerce. The principal exports from Sicily are corn, nuts, hemp, flax, senna, oil, wine, sulphur, fish, silk, and fruits, the whole amount of which is said not to exceed 11,000,000 ducats, or about £240,000 Sterling.‡ The imports, which consist of colonial produce, hardware, jewellery, lead, and manufactured articles, are estimated at the same sum as the exports. Money accounts are kept in ounces, taris, and grains.

1 Grain equal to ¼ Sterling.
20 Grains equal to 1 tari, or 5d. Sterling.
30 Taris equal to 1 ounce, or 12s. 6d. Sterling.

Sicily abounds in valuable minerals. Mineral springs, both hot and cold, frequently occur. Iron and copper are found in the region of Ætna, and cinnabar sulphur, alum, nitre, and sulphate of iron also occur. A large mine of coal has been discovered near Messina, and salt mines have been found near Castro Giovanni in the middle of the island. The quarries of marble

* Very minute and interesting details respecting this earthquake will be found in Dr. Brewster's *Edinburgh Journal of Science*, vol. iv. p. 1[illegible]5, and 362, where the reader will find a translation of Professor Ferrara's Memoir upon these earthquakes.

† A full account of the productions of Mount Ætna will be found under that article.

‡ Another account states that the exports do not exceed £1,500,000. This discrepancy must be founded on some typographical error.

are numerous, and good building stone is found in almost every part of the island. Porphyry, jasper, and agates likewise occur.

Sicily used to be governed by a viceroy, in whose absence the archbishop of Palermo was regent. The parliament, before its reformation in 1810, was composed of three branches, viz. 229 nobles, 66 prelates, and 43 demaniale or deputies from cities, universities, and crown estates. Out of each of these branches four deputies were chosen to conduct the public business. The ecclesiastical government is in the hands of three archbishops and seven bishops. The administration of justice was in a very deplorable state, and of this we have given some examples in our article on Catania. During the residence of the British army in Sicily from 1806 to 1816, very essential reforms were introduced both into the Sicilian parliament and the administration of justice, and we trust that these salutary changes will not be permitted to go into desuetude.

In the year 1820, the revenue of the island amounted to 1,637,332 ounces, and the expenditure to 1,665,355 ounces. The expenses are limited to 1,817,680 ounces, out of which 150,000 ounces are employed to pay that part of the debt which bears no interest, and when that is discharged, this annual sum is to form a sinking fund to extinguish the debts which do not bear interest, but the amount of which is not publicly known.

The Sicilian army amounts to about 10,000 men, including cavalry, infantry, and artillery, and in addition to this, there is a militia of 8000. The navy consisted formerly of 1 ship of the line, 2 frigates, 5 sloops, with numerous gunboats, but more recently it has been united with the Napolitan navy. Many of the officers were paupers, and so small was the pay of the troops, that, in years of scarcity, the soldiers were dependent on public charity.

The Sicilians bear a striking resemblance to the Italians and Spaniards, not only in their complexion and general aspect, but also in the indolence of their habits, the licentiousness of their morals, and their passion for gaming and public amusements. Education was for some time an object of interest in Sicily. The colleges of Palermo and Catania have already been referred to in this article, and are on a very imperfect footing. The Normal schools established in 1789, are on a better footing. The pupils are limited, and the qualifications of the teachers are previously ascertained. At the age of nine, girls are put to a convent, where, for about seven years, they are taught reading, writing, and the ceremonies of their religion. Several schools on the system of Bell and Lancaster have been recently established, and there is reason to hope that an improved system of public instruction will banish the ignorance, credulity, and superstition, which so peculiarly visit the Sicilian mind. The religion of Sicily is of course catholic; and the number of ecclesiastics has been computed at 70,000, exclusive of a still greater number of monks and nuns.

For an account of the history of Sicily, see our articles Italy, Naples, and Messina.

For farther information respecting this island, see the works quoted under our article Ætna, Watkin's *Travels through Switzerland, Italy, Sicily, &c.* Munter's *Memoirs relative to Naples and Sicily*, Vaughan's *Views of the Present State of Sicily*, 1812, Thompson's *Sicily and its inhabitants*, 1815, and Smyth's *Sicily and its Islands*, 1823. See also our articles Catania, Messina, and Palermo.

SIENITE, See Mineralogy Index.

SIENNA, or Siena, an ancient city of Italy in Tuscany, and capital of a province of the same name, is pleasantly situated on three hills. The streets are consequently uneven, winding, and narrow, and a great part of the town impassable for carriage. The town is about 5 miles in circumference, and has a very imposing aspect when approached from the south. The houses are in general built with brick, and the streets are paved with the same. The only public square that is reckoned handsome is that which contains the town-house, and also a beautiful fountain. The cathedral is a noble gothic building, begun in 1284 and finished in 1333. It is faced both within and without with white and black marble, and considered next in grandeur to St. Peter's. The nave is supported by rows of beautiful columns, and its pavement is decorated with mosaics. The front is prodigiously loaded with ornaments, and the marble sculpture on the pulpit, and the carving in wood on the choir are much admired. Many of the chapels and altars, which are extremely rich, are decorated with beautiful paintings and statues. The church of St. John's, which lies directly underneath the cathedral, may be seen from an opening in the pavement of the choir. The entrance is without on the hill, and the cathedral may thus be said to stand on the church of St. John's.

The town-house already mentioned, is a large Gothic building, surrounded with porticos. The castle, built at an extremity of the city, is not a place of great strength. The university contains 60 professors. It was founded by Charles V. who conferred particular privileges on the German students. An academy of physics and natural history established here, acquired some celebrity from their published memoirs. Near the castle, the university has an academy for martial exercises. A great number of the gentry and literati reside in Sienna; and the town has acquired a reputation for politeness, for a taste for literature and the arts, and for the purity of the Italian which is spoken. The archbishop's palace stands near the cathedral, and opposite to it is a large and well endowed hospital, founded by a shoemaker. Sienna contains many palaces, fountains, churches, and convents. In the Venhuini Chapel of the churches of the Dominicans, is an ancient picture of wood, representing the Virgin with the infant Jesus, by Guido Janese, dated 1221. The manufactures carried on here are very trifling. They consist of woollen goods, hats, leather, and paper. There is a little trade in corn; and the marble quarries in the vicinity might be rendered valuable by enterprising capitalists. One of the principal objects of interest to strangers is the Piazza, a large extent of ground laid out in walks, and decorated with statues. It is the place of public resort in the evening. The esplanade is an avenue leading to the citadel, the ramparts of which are planted with trees, and laid out in the form of terraces.

Sienna is mentioned by Pliny under the name of *Colonia Senensis*. During the middle ages, it enjoyed great prosperity, and was more populous than at present. The territory was once a free republic, but was conquered by Charles V. The Siennese, a territory of Sienna, is now a province of the Grand Duchy of Tuscany. It is about 62 miles long, and contains 34,000 square miles, and 190,000 inhabitants. The population of the town is about 24,000. East long. 10° 15′, north lat. 43° 22′.

SIERRA LEONE, the name of a British settlement on the west coast of Africa. It derives its name from the river called the Mitomba, or Sierra Leone, which traverses it, but the origin of which has not been explored. The territory of Sierra Leone lies both on the north and south side of the river. The country on the north is low and flat, but that on the south speedily rises into a long mountainous ridge, which, from being the residence of lions, gave the name of Sierra Leone to the river. From this ridge descend many mountain streams, which unite in the Bay of France, a large basin, which is the best watering place in the whole coast of Guinea, and which is described as a most delightful and picturesque spot.

The general aspect of this country is that of an impenetrable forest, a few small portions of which only have been cleared and cultivated. Rice is raised on those grounds which are capable of irrigation, and forms the food of the rich, while millet, yams, and plantains, are raised by the poor. The principal fruits are pine apples, oranges, lemons, limes, &c. and a fruit like the melon. A wholesome liquor is obtained from the palm tree.

The woods and mountainous regions abound with animals, particularly lions; apes occur in great quantities. Serpents are particularly numerous; and the river abounds with large alligators, and contains a species called the monatea, or sea cow. Among the articles of trade here, may be enumerated elephants' teeth, which are remarkable for their size and perfection. A considerable quantity of civet is likewise brought to market here.

The colony of Sierra Leone consists of *sixteen* small towns or villages, the population of which, in 1818, was 9565, whereas in 1820, it had risen to 12,509, and in 1825, it was estimated at 18,000. The following is a list of the towns and villages, with their population, according to the census of 1820.

	Population.
Freetown and suburbs	4,785
Leopold, township	469
Charlotte, township	268
Bathurst	469
Gloucester	563
Regent town and vicinity	1,218
Kissey and vicinity	1,033
Wilberforce	409
Kent and vicinity	296
Waterloo	395
Hastings	195
Wellington	456
York	297
Leicester Hamlet	78
Villages in Peninsula	1,468
Peninsula and the islands	115
Island of Gambia	37
The population in 1820	12,509

This population consists of	
Males	5,796
Females	3,020
Boys	2,015
Girls	1,678

The different nations to whom this population belongs may be arranged as follows:

Negroes liberated	8,076
Natives	2,939
Nova Scotians	730
Maroons	594
Europeans	120

The principal town of this colony is Freetown. The next town in importance is Regent's Town, established in 1813. When this town was visited in 1816 by Mr. Johnson, the missionary teacher, he found it occupied by 1100 captured negroes from 22 different nations. The most deadly enmities prevailed among them. Some lived in the woods, subsisting by plunder, and in stealing fowls, which they ate raw. When clothes were given them, they either threw them away or sold them. Destitute of the idea even that marriage was a tie, they were addicted to the most shameful debaucheries, and, crowded together in their miserable huts, they contracted various diseases, of which several died every day; and, in the first years of the colony, there were only six births among these 1100 individuals. A deplorable superstition prevailed among them. They erected numerous chapels in honour of the evil spirit. Nothing could induce them to cultivate the fields, and the few that did exercise that species of industry, had their crops destroyed by their neighbours. By the exertions of Mr. Johnson, and a few intelligent negroes, the most remarkable improvements were effected.

The negroes were at length civilized; they now lead a quiet and laborious life. They frequent divine service. Several of them partake of the sacrament, and many of them lead a truly Christian life. By their industry, Regent's Town has been laid out with great regularity. Nineteen new streets have been formed, and good roads made in its vicinity. Among its buildings there is already a good church built of stone; a government house, a house for the clergyman, a bridge of several arches, school-houses and warehouses, and many of the houses of the natives are built of good stone. All of the people are farmers. Every house has an enclosed garden attached to it. The land in the vicinity is cleared and under cultivation, and in some places even to the distance of three miles. Vegetables, and all the finest fruits of the torrid zone, are raised in abundance, and of domestic animals there is an ample supply. Many of the negroes, at the same time, carry on trades. In 1818 there were 50 masons and bricklayers, 40 carpenters, 30 sawyers, 30 shingle makers, 20 tailors, 4 blacksmiths, and 2 butchers. In that way upwards of 600 negroes provided for their own maintenance. The females have learned to make their own clothes. In 1818 about 400 couple had been married. About 1400 attend divine service; and the schools, which began with 140 children and 60 adults, now contain above 500 scholars.

The excellence of the moral and intellectual qualities of the pupils, suggested to the society belonging to the Church of England, the establishment of a seminary called the *Christian Institute*, where the young natives may be prepared for the missionary service. This establishment, at first founded at Leicester, was afterwards transferred to Regent's Town, and it now contains a considerable number of pupils from 12 to 18 years of age. Several of them who have already gone out have paved the way for the missionaries in the interior of Africa. They carried along with them the first elements of civilization, and disposed their less cultivated brethren to submit to the discipline of Christianity.

The townships of Charlotte, Leopold, Gloucester, and Wilberforce, are in the immediate vicinity of Freetown, and, along with Freetown, contains upwards of 2000 scholars in a regular course of instruction.

In consequence of these accessions to the population, four new and more distant stations have been founded since 1818, viz. Waterloo, Wellington near Kissey, Hastings, and York. The three first are on the eastern side of the colony, while York is on the south-west side, bordering on the Sherbros, among whom a settlement called Kent had already been formed.

In connexion with the colony of Sierra Leone, a settlement called Bathurst has been established at St. Mary's, at the mouth of the river Gambia, and to the north of Sierra Leone. In 1820 the population was only 469; but it is now 2000. The natives are all Mahometans. The climate is healthy, and provisions are much cheaper than at Sierra Leone. From the opportunities which it has of communication with the populous countries on the Gambia, it will, no doubt, become an important station for commercial enterprise. The missionaries who reside here have been sent out by the Wesleyan Society.

About eight miles from Bathurst the quakers have formed an establishment at Birkow, a place in the country of the Mandingos, on Cape St. Mary. A young negro has opened a school at Birkow, for the instruction of children of both sexes.

Since the year 1822 the Americans have founded a colony at the mouth of the river Mesavada, to the south of Sierra Leone. This colony has been called Liberia, and the principal town Monrovia. The population consists of African-Americans, and of free negroes.

The following were the number of scholars educating in the year 1820, at the different establishments in Sierra Leone. Since that time we know that they have very greatly increased; but the exact increase we are not acquainted with:

Freetown and Islands	575
Regent Town	432
Gloucester	258
Kissey	158
Leopold	154
Bathurst	113
Charlotte	106
Waterloo	86
Kent	77
Wilberforce	75
Hastings	57
Wellington	16
	2107

The first settlers in Sierra Leone were the Portuguese. The English afterwards established a footing in Rance Island in the middle of the river; but it was not till near the end of the eighteenth century that the negro colony was established. In 1783, Dr. Smeathmar suggested the idea of it. After the American war, a number of negroes who were discharged from the army and navy, were collected, to the amount of about 400, and along with about 60 whites, they were embarked on board transports, furnished by government, and were conveyed to Sierra Leone, where they arrived on the 9th May 1787, with arms, provisions, and agricultural implements. Captain Thomson of the Nantilus purchased a piece of ground 20 miles square from King Haimbanna. A proper site for a town, called Freetown was chosen, occupying a rising ground fronting the sea. When the lands were divided among the colonists, they abandoned themselves to indolence and vice: and the consequence of this was, a dreadful mortality, which reduced them to 276. In addition to that calamity, the town was plundered in November 1789, by an African chief, who compelled the colonists to seek for shelter in Rance Island. In 1791, Mr. Falconbridge went out with a supply of stores. He collected the scattered colonists, and having persuaded the native chiefs to cede again the former territory, a new site for the colony was chosen at Granville town. While these things were going on, the original African Association (See article Association. Africa.) was incorporated by act of parliament in 1791, with a charter for thirty-one years. They immediately sent out five ships with stores, articles of trade, and several new settlers. A considerable number of whites and free negroes, to the amount of 1200, who had taken shelter in Nova Scotia, after the American war, accepted of the offer of the company to go to Sierra Leone; and they arrived there in 1792. Freetown was again made the capital of the colony, and for some time it flourished. Discontents, however, soon arose, and complaints were personally made to the Company by the Nova Scotian negroes, respecting the lowness of their wages, and the high price of the Company's goods. When these dissatisfactions were removed, the town was plundered in September 1794 by a French squadron, and the colonists were thrown into the most destitute condition. The Company, however, repaired this disaster: but so great had been their losses, and so profuse the expenditure, that they found it prudent to make an arrangement with government, by which Sierra Leone was placed like other colonies under its jurisdiction.

The establishment of the African Institution about that time for the improving the condition of that vast continent, induced government to place Sierra Leone under its management. The method which they have adopted for recruiting its population was, to send to the colony all the negroes captured by the vessels sent to put a stop to the slave trade. From this source of supply, the colony has rapidly increased in numbers, and the colonists now enjoy all the advantages of English law. From the unhealthiness of the climate, and the smallness of the salaries allowed, it has been found difficult to get qualified persons to fill the official situations; but these evils have gradually diminished, and the colony has prospered in the manner which we have described in a preceding part of this article.

Its tranquillity has been very recently disturbed by the surrounding native powers: and unless some more effectual means of defence are provided, there is reason to fear that it may yet fall under their repeated assaults.

Since the above article was written, government has, we understand, resolved to abandon Sierra Leone, and to remove the colony to the island of Fernando Po, where the new buildings for the accommodation of the troops and the civil authorities are already in a state of progress.

SIGHT. See Optics, and a popular treatise by Dr. Brewster, *on the Defects of Sight, and on the means of removing them*—now in the press; and also Science, Curiosities in.

SIGNALS. See Telegraph.

SIKHS. See India. See also Sir John Malcolm's *Sketches of the Sikhs*, in the *Asiatic Researches*.

SILESIA. See our article Prussia, and a short notice in the same article, *note*.

SILICA. See Chemistry Index, and Mineralogy Index.

SILHET, an extensive country of Bengal, on the east of the Burrampooter. It consists of bleak mountains and level plains, which are generally laid under water in the rainy season. Great crops of rice are produced. It is traversed by several rivers, the chief of which are the Megna and the Soormah. They abound with fish, and during the rainy season boats may sail over a great part of the country. Its chief exports besides rice, are lime, ivory, timber, oranges, fragrant aloe wood, and a kind of wild silk called Muggadooties. Elephants are found in the woods, but they are not deemed valuable. The principal town is Silhet or Sirihat, the capital of Azmerigunge. In 1801 the population was 492,495, there being two Mahommedans for three Hindoos.

SILIUS Italicus Caius, a Roman poet of some celebrity, was born about A. D. 15. He is supposed to have been born at Italica in Spain; but he spent most of his life in Italy where he possessed several estates. He was consul at the time of Nero's death, and possessed the friendship of Vitellius. After discharging the duties of proconsul in Asia, he retired into private life, and spent his time in adorning villas which he quitted for new ones. He spent the latter part of his life at his seat in Campania. In his 75th year he was attacked with an incurable ulcer, and it is stated that he died of abstinence from food.

His only work is an epic poem on the second Punic war, the best editions of which are those of Drakenborch in 4to. *Utr.* 1717, Lefebvre de Villebrune in 1782, in 4 vols. 12mo.

SILISTRIA, or Dristra, a town of Turkey in Bulgaria. It stands on the south of the Danube, and is well fortified and tolerably built. It contains several elegant mosques and baths. Population 20,000. East. Long. 27° 6', North Lat. 44° 15'.

SILK, the name given to a soft, delicate, and shining fibre, the production of different species of larvæ or caterpillar. It is most commonly produced by the *Phalaena bombyx*, though the *Phalaena atlas* is said to yield it more abundantly.

The ancients knew little concerning this substance. The manufacture of silk, including the rearing of the worms, was introduced into Europe in A. D. 555 by two monks, who, under the patronage of Justinian, brought great quantities of the worms from India to Constantinople. Athens, Thebes, and Corinth, established manufactories of silk, and from them the Venetians supplied the west of Europe for many centuries with it. From Greece the art passed to Palermo and Calabria, from which it was propagated through Italy and Spain. It came into France a little before the time of Francis I.; and in 1489 it was introduced into England, though so early as 1455 there was a company of silk-weavers.

The silk worm seems to be a native of China, where it has been reared from a very remote period. The insect remains for nearly six months in its egg, which is about the size of a pin's head. From this it emerges in the form of a caterpillar, with eight pair of feet. It now feeds on the leaves of the mulberry or lettuce, and it increases so rapidly in size, that in six or seven days after birth its skin bursts, and the insect appears in a new form, advancing for seven days more to another stage. When the worm is about to quit its *fifth* skin, it then winds for itself a silken bag or cone about the size and form of a pigeon's egg, called the *Cocoon*. Here it throws off its last skin, and in twenty days after the transformation of the larva into the chrysalis, which is effected within the cocoon, it becomes a moth with white wings. This moth lays eggs, and these eggs about six months after produce larvæ as before.

It has been stated, that a fibre of silk uncoiled from a cocoon is 406 yards long, and weighs when dry three grains. One lb. avoirdupois would extend 535 miles, and forty-seven pounds would encircle the globe.

The method of rearing the silk worm may be thus shortly described:—The eggs being laid upon shallow trays of brown paper, the chopped leaves of the white mulberry are strewed over the trays. In its second or third stage, the larvæ are taken to larger trays, placed in a small compartment, where the temperature is about 75° Fahr., and an increased quantity of the leaves given them, as will appear from the subsequent tables of Count Dandolo. The trays are now removed to a large apartment, where the temperature, at first about 72° Fahr., is allowed to diminish gradually to 69°.

When the cocoons are ready, the *nymphæ* within these, intended for silk, are destroyed by putting them in boiling water, and they are afterwards dried by artificial heat; but those designed for the future crop are laid out in a coarse linen cloth stretched on a table in a room not used and dark. From every lb. of cocoons (male and female) two ounces of *ova* or *eggs* may be obtained by Count Dandolo's method, as afterwards exhibited in the tables, where, if the management is bad, from ten to 30 lbs. may be sacrificed for a single oz. of eggs. In order to ascertain the cocoons in which the *nymphæ* are perfect and sound, we must see if the extremities of it are less abundantly supplied with silk, and if it is confusedly arranged; when this is the case, the nympha is likely to be sound.

The male are distinguished from the female nymphæ by the greater size of the latter, so that the female cocoons are likely to be larger than the male. The weight of 1000 male cocoons is 1700 grains, while that of as many female ones is 3000 grains.

When a proper number of each has been selected, those intended for moths are placed, as already mentioned, on a cloth in a room whose temperature does not exceed 72°, a higher temperature occasioning unhealthiness. Stillness and diminished light are considered favourable. When the moths have deposited their eggs on the cloth, they soon die, and the ova adhere to the cloth by a silky gummy substance. The temperature is now brought down to 66°, and when the colour of the ova has changed to ash-colour, the cloth stretched on a frame may be removed to a cool apartment, where the eggs should be kept dry. When the eggs are required, they are detached by immersing the cloth in fresh water, which dissolves the mucilage. The ova are then dried with care.

The uncoiling of the silk from the cocoons is effected by collecting the ends of the threads, and winding them on reels, the greatest care being taken that the uncoiling goes on freely through all the extent of the cocoon. This effect is promoted by throwing them into caldrons of water nearly boiling. The threads are then collected by a whisk or brush, and passing through plates of steel they are wound upon a reel by machinery, attached to a water wheel, or any other power.

"Gensoul of Italy," says Mr. Murray, "has invented an apparatus by means of which the water is heated through the medium of steam, and the nymphæ that fall are collected on a grating of iron wire at the bottom of the boilers, which is frequently raised for the purpose of removing the husks. By this ingenious method much fuel is saved, one furnace with its boiler serving to heat twenty vessels, and from the decreased temperature the cocoons do not suffer any decomposition or change, as is the case in the ordinary way wherein they are immediately exposed to the direct agency of the fire. Another saving might still be effected by this method, in the substitution of vessels or cisterns of wood for boilers of copper. In the month of August last, at Buffalora, on the Milanese frontier, I visited an establishment for unwinding the silk. Women were arranged in two rooms, opposite each other, and conducted the process. The cocoons contained in baskets on one side were thrown by handfuls into caldrons of water, kept boiling by charcoal fires beneath. Each by a *whisk* (of peeled birch) collected the threads *en masse*, the first confused portions were rejected, till the threads unwound regularly, freely passing over glass-rods to prevent the injuries of friction. The first portions are necessarily useless, and are separated by the hand. When the threads came off uniformly, the cocoons were raised suspended to the hand by their respective threads, and thus handed over to those on the opposite side, who, in their turn, threw them into caldrons of water, the temperature of which was nearly that of blood heat, and more than milk warm—thus sustained by a steam pipe. The water was thus kept clear, and the silk preserved pure and unsoiled. From these the threads were finally wound. The proprietor informed me that this establishment cost 60,000 francs."

The following tables, containing a general view of the process carried on, and the results obtained by Count Dandolo, were abridged by Mr. John Murray from Count Dandolo's work, and first published in Dr. Brewster's Journal of Science, No. III, p. 59, Jan. 1825. The zero of Bellani's hygrometer corresponds with that of Saussure.

Fifth Period - -		3820 0				

Management of the Silk-worms, produced from five Ounces of Ova.—Continued.

Fifth Period, - -	3820	0
Fourth Period, - -	620	0
Third Period, - -	216	0
Second Period, - -	55	0
First Period, - - -	20	0
Leaves devoured, -	4731	0
	400	0
	290	0
Total,	5421	0

For each ounce of ova, 1084 lbs. of leaves have been taken from the tree.

The silk-worms, from five ounces of ova, have consumed the above 5421 lbs. of leaves, and produced 401 lbs. of cocoons, &c.

For each pound of cocoons there have been consumed about 13½ lbs. of mulberry leaves.

The Temperature required for the Production of the Silk-worms from the Ova, anterior to 23d May, 1814.

1814. Month	Internal Temperature.	External Temperature.	1814 Month	Internal Temperature.	External Temperature.
May 11	Fa. 63.50	Fa. 50 26	May 18	Fa. 70.25	Fa. 50.00
12	63.50	45.50	19	72.50	50.00
13	63.50	45.50	20	74.75	52.25
14	63.50	45.50	21	77.	52.25
15	65.75	47.75	22	73.25	54 50
16	65.75	52 25	23	81.50	52.25
17	68.	50.00			

The external temperature was ascertained at five o'clock, every morning, from a western exposure.

During the thirteen days in which the silk-worms were developed from the ova, 134 lbs. of food were consumed. The lb. of 28 ounces is to be understood, or 2 lbs. Troy equivalent to 0.7625 kilogrammes of France.

The following is the Daily Decrease in Weight of 1000 *ounces of Cocoons in a Room, the Temperature of which was from* 70° 25 *F.* 72° 50 *F.*

Day 1st,	1000 oz.		Day 7th,	960	less 6.
2d,	991	less 9.	8th,	952	less 8.
3d,	982	less 9.	9th,	943	less 9.
4th,	975	less 7.	10th,	934	less 9.
5th,	970	less 5.	11th,	925	less 9.
6th,	966	less 4.			

So that the 1000 ounces have lost in 10 days, during the mutation, 75 ounces. There is a gradual declension for the first five days inclusive, and a regular gradation for the last five days.

8 oz.	of ova have lost	in 5 days	in wt.	100 gr.	in 8 days	360,	& in 10 days	410.
6 oz.	do.	do.	do.	86 gr.	do.	172,	do.	248.
5 oz.	do.	do.	do.	60 gr.	do.	168,	do.	216.
4 oz.	do.	do.	do.	80 gr.	do.	161,	do.	224.

Each grain contains about 68 ova, and an ounce weight 39,168 ova. The *oncia Milanese* contains 575 grains. The above number is to be understood of *fecundated* ova. Those which are badly impregnated contain 43,080, and are of a *reddish* colour: and of those not at all impregnated, and of a *yellowish* tinge, there are in the ounce 44,100.

The Expense of the Contingencies of the 5 *ounces of Crop in* 1814, *are thus calculated by Count Dandolo.*

Cost of 5 ounces of ova, - - - - -	15.
Wood for fuel - - - - - - -	1.15
5500 lbs. of leaves of the mulberry at 7 lire per 100 lbs.	335.
Expense of gathering the leaves, - - -	96.5
100 lbs. light and heavy wood, at 32 soldi - -	32.
Supplemental husks, - - - -	4.10
Supplemental paper, - - - - - -	4.
Oil for light, - - - - -	9.

Preservative phial, - - - - - - -	1.10
Daily labour, - - - - - - -	100.
Lire Milanese,	612.
Interest, &c. on capital, - -	90.
Total expense -	612.
401 lbs of cocoons obtained, which, being sold at 78 soldi per lb. produced, - - -	1,563.18
Nett profit, -	Lire 831.18

Note.—A *Lira Milanese* is equal to about 8d. and there are 20 *Soldi* in a *Lira M.*

The calculation, as above, includes not only interest on capital, but a valuation on the mulberry leaves, which is about one-half of the total expense.

The Augmentation and Diminution of the Silk-worms in Weight and Size.

Increasing Progression.	Weight.	*Increasing Progression.*	Weight.
100 ova weight about	Grain 1	The ova in the 1st instance, say	1 line
After the 1st change, about	15	After the 1st change, length say	4
2d change, say	94	2d change, -	6
3d change, say	400	3d change, -	12
4th change, say	1628	4th change, -	20
5th change, say	9500	5th change, -	40

Note.—In 30 days the silk-worm has increased in weight 9500 times; and, in 28 days, the animal has augmented in size about 40 times.

The French Line is equal to 1.67 Lines English, calculated 100 Lines English to the inch.

Decreasing Progression.

	Grains.
100 Silk-worms, at their greatest size, weigh about	7760
100 chrysali weigh - - - - - -	3900
100 females weigh - - - - - - -	2990
100 males weigh - - - - - - -	1700
100 females, after the ova are deposited, weigh -	980
100 females, naturally dead, and the eggs or ova deposited, &c. - - - - - - -	350

In the space of about 28 days more, the silk-worm has diminished in weight about 30 times. Thus, the length of the silk-worm from the time of its greatest increase to the moment it is converted into the chrysalis, has diminished about three-fifths. The chrysalis is the intermediate state between the caterpillar and the winged insect. The *larva* emerges from the ova, spins its cocoon or domitory, and therein passes into the state of the *pupa*. It finally emerges from thence the *imago*, or winged insect, which dies so soon as the ova are deposited.

Space occupied by each ounce of Ova cultivated.

In the first age, an area of square Braccia,	4
In the second, an area of ditto -	8
In the third, an area of ditto -	19
In the fourth, an area of ditto -	45
In the fifth, an area of ditto -	100

Note.—The *Braccio di Milano* is divided into 12 *ounces* or inches, and corresponds to 5.95 palms, which may be calculated at 22 English inches nearly.

Amount in Weight of Mulberry Leaves consumed by the Silk-worms. 1073 lbs. of Leaves, for every ounce of Ova, have been consumed, divided as follows, viz.

First age, eaten -	lbs. 4	Leaves, &c. destroyed unused.	
Second do. -	12	In first age,	lb. 1
Third do. -	40	In second do.	2
Fourth do. -	120	In third do.	6
Fifth do. -	732	In fourth do.	13
	lbs. 908	In fifth do.	68
			lbs. 95

In the course of the management of the silk-worms, the 1073 lbs. of leaves from the tree (from evaporation, and other causes) will have lost 70 lbs.

Note.—There have been devoured by the silk-worm about 515 lbs. of pure mulberry leaves. The 1073 lbs. of leaves as taken from the tree will yield [illegible] lbs. of cocoons, calculating from one ounce of ova.

The artificial heat necessary in Count Dandolo's process, is kept up by a stove of tile, those of iron being injurious. The necessary dryness of the air may be produced by absorbent substances, and when it is too dry, shallow vessels of water are placed on the floor.

SIMPSON, Thomas, a celebrated English mathematician, was born at Market Bosworth in Leicestershire, in 1710. He was brought up to his father's profession of a weaver, but such was his love of study, that he soon quitted his profession and supported himself by teaching a school. An absurd propensity for astrology, while it rendered him a sort of oracle in his neighbourhood, involved him in some difficulties, which obliged him to remove to Derby, where he continued some years, following his trade in the day, and teaching a school in the evening. Notwithstanding his industrious habits, he found it difficult to provide for his family, and he was then induced to remove to London in 1736. Here he followed his business in Spittalfields, and taught mathematics at his leisure hours, and so great was his success, that he brought his wife and three children to London, where he settled himself permanently.

His first work was a *New Treatise of Fluxions*, which was published by subscription in 1737, and such was its reception, that, in 1740, he published *A Treatise on the Nature and Laws of Chance*, which was followed in the same year, with his *Essays on several curious and interesting subjects in Speculative and Mixed Mathematics*. These works extended his reputation even to foreign countries, and he was elected a member of the Swedish Academy of Sciences. His *Doctrine of Annuities and Reversions*, appeared in the same year, and an *Appendix* to it in 1741. Supported by the influence of Mr. Jones, the father of Sir William, our author was, in 1743, appointed professor of mathematics in Woolwich, and in the same year he published his *Mathematical Dissertations*. In 1745, he was admitted a fellow of the Royal Society, having been excused his admission fees on account of his limited income. In 1744, he published his *Treatise on Algebra*, which was enlarged in 1755. In 1747, he published his *Elements of Geometry*, which was reprinted in 1760, and subsequent years. In 1748, Mr. Simpson printed his *Trigonometry Plane and Spherical, with the Construction and Application of Logarithms*. His *Select Exercises for Young Proficients in Mathematics* appeared in 1752, and his last work, viz. his *Miscellaneous Tracts*, came out in 1757.

Mr. Simpson was likewise the author of several papers which appeared in the Philosophical Transactions, and he edited the Lady's Diary from 1754 till 1760, a work to which he had been a contributor since 1736, and which he raised to a very high degree of respectability. By the closeness of his application, his health began to suffer. A languor of mind and body supervened, and the vexation arising out of a difference with one of his colleagues exaggerated the calamities under which he suffered. In February, 1761, he set out for Bosworth, to seek in his native air the elements of health, but he gradually grew worse, and expired on the 14th of May, 1761, in the 51st year of his age.

SIMSON, ROBERT, M. D. a celebrated Scotch mathematician, was born on the 14th October, 1687, O. S. at Kirktownhill, Ayrshire, a small property which, for some generations, had been the residence of his immediate progenitors. He was the eldest son, and was educated at the university of Glasgow, where he devoted his attention principally to the philosophy and theology of the schools, and such was his progress that, at an early age, during the illness of the professor, he taught the class of oriental languages.

While he was studying theology at the divinity hall he took a fancy for mathematics, and amused himself occasionally with this new study; but it soon gained upon his affections, and it was not long in supplanting his passion for theology. He accordingly abandoned himself wholly to the study of geometry, preferring the sure methods of the ancients to the analytical method which had now so many supporters.

At the early age of twenty-two, the members of the college offered him the mathematical chair in the University of Glasgow, in which a vacancy was soon expected. Reluctant, however, to advance at so early an age from the situation of a student to that of a professor in the same college, he solicited and obtained permission to spend one year in London. Here he became acquainted with Mr. Jones, Mr. Caswell, and Mr. Ditton, who gave him ample information respecting the progress of mathematics both in England and on the continent of Europe. When the vacancy in the mathematical chair occurred in 1711, he was unanimously elected, after giving a specimen of his skill in mathematics, and of his dexterity in teaching geometry and algebra.

Immediately after his admission, which took place on the 20th November, Mr. Simson entered upon the duties of his class with much zeal and success, and, instigated by the advice of Dr. Halley, he directed his private studies to the restoration of the ancient geometers. His first labour was to restore the Porisms of Euclid, the history of which we have already given in our article PORISMS. The next object of his labour was the "Loci Plani" of Apollonius, which he completed in 1731, but which he did not venture to publish till 1746. Notwithstanding all this caution, he recalled all the copies in the hands of his bookseller, and kept the impression by him for several years. He afterwards revised and corrected this work, which greatly extended his reputation, and obtained him a high place among the geometers of his age.

In 1750 our author published his *Sectionum Conicarum libri Quinque*, a work which he intended as an introduction to the study of Apollonius.

The restoration of the elements of Euclid was the great object of Dr. Simson's care; and, along with the data, he published this valuable work in 1750.

The *Sectio Determinata* of Apollonius next occupied his attention; but this work was not published till after his death, when it was printed, along with the Porisms of Euclid, and published at the expense of Earl Stanhope.

"As he never entered into the married state, and had no occasion for the commodious house in the university, to which, as professor, he was entitled, he contented himself with chambers spacious enough for his own accommodation, and for containing his large, but well selected collection of books, but without any decoration or even convenient furniture. His official servant acted as valet, footman, and bed-maker; and as this retirement was entirely devoted to study, he entertained no company at his chambers; but on occasions when he wished to see his friends, he repaired to a neighbouring house, where an apartment was kept sacred to him and his guests. He enjoyed a long course of uninterrupted health, but towards the close of life he suffered from acute disease, which obliged him to employ an assistant in his professional labours. He died on the 1st of October, 1768, at the age of 81, leaving to the university his valuable library, which is now kept apart from the rest of the books. It is still regarded as the most complete collection of mathematical works and manuscripts in the kingdom, many of them being rendered doubly valuable by the addition of Dr. Simson's notes. It is open for the public benefit, but the use of it is limited by particular rules and restrictions. Dr. Simson was of a good stature, and he had a fine countenance, and even in his old age he retained much gracefulness and dignified manner. He was naturally disposed to cheerfulness; and though he seldom made the first advances towards acquaintance, he always behaved with great affability to strangers." Those who wish for a more particular account of the life and writings of this able geometer, we must refer to "Dr. Trail's *Account of the Life and Writings of Dr. Simson*," Lond. 1822, a work of great ability and interest. See also our articles ANALYSIS, EUCLID, and PORISMS.

SINAI, Mt. See ARABIA.

SINDE, SINDY, or SCIND. See INDEX.

SINES. See TRIGONOMETRY.

SINGAPORE, or SINCAPORE, is a town situated on a small island of the same name at the southern extremity of the Malay peninsula.

The town and principality were founded by adventurers who emigrated originally from Sumatra, and it was a place of little importance till 1819, when a British settlement was formed there under the direction of Sir T. S. Raffles, Lieutenant Governor of Bencoolen.

The town, though still in its infancy, is rapidly extending according to a regular plan adopted some years ago. It is built near the shore, and the part of it devoted to trade stretches along an inlet of the sea, about 300 feet wide at its mouth, and affording a safe and well sheltered harbour. Several parallel and cross roads extend from this over the plain, which is occupied chiefly as a military cantonment. Behind the cantonment is a hill on which it is intended to erect a government house.

The rapid rise of this important station, says Sir T. Stamford Raffles in a letter written in 1822, is perhaps without a parallel. When I hoisted the British flag, the population scarcely amounted to 200 souls. In three months, the number was not less than 3000, and it now exceeds 10,000, chiefly Chinese. No fewer than 173 vessels, principally native, arrived and sailed in the first two months. The following is the state of its trade in 1822:—

Exports,	66,978 Tons.	
Imports,	63,661	
Total,	130,639	
Number of vessels importing in 1822,		1,593
Ditto exporting in do.		1,733
Total,		3,326
Value of Imports in 1822,	3,610,206 Dollars.	
Exports do.	3,172,332	
	6,782,538	
Not in official returns,	1,713,639	
Total Exports and Imports in Dollars,	8,496,177	

The interior of the island exhibits a succession of hill and dale, covered with wood. The soil is fertile, the water good, and the climate cool and healthy. The mean annual temperature of Singapore for 1822 was 80° 18, and for 1823 79° 81, giving a mean of 80°.* In 1822, there were 218 rainy days, and in 1823, 208. The mean annual height of the barometer for these two years, was 29.91 English inches. An account of the method of collecting the Fucus Saccharinus, (or *agar-agar*) on the coral shoals, near Singapore, and of preparing it for the Chinese market, will be found in Dr. Brewster's Journal of Science, No. XV. p. 162.

The Straits of Singapore consist of innumerable little islands of various shapes, and covered with wood, indented with little bays and caves, in which the finest turtle abound. At the east end of the Straits, lies the rock of *Pedrabanca*, so called from its being covered with the white excrements of birds. Among the animals at Singapore we may mention the halicora dugong, the flying squirrel, and the galeopithecus variegatus. The junks which visited Singapore in 1821, when Mr. Finlayson was there, were from Canton, Amoy, Cochin China, and the islands to the east. The larger ones were from 200 to 300 tons burden. They had neither chart, nor book of any kind, but merely a rude compass. A newspaper, called the Singapore Chronicle, is published here. See Finlayson's *Mission to Siam and Hue*. Lond. 1826, p. 45-77. East Long. 104°, and North Lat. 10° 24'.

SION, or SITTEN, the *Civitas Sedunorum* of the Romans, is a town of Switzerland. and capital of the Canton of Valais. It is situated on the Rhone, at the foot of three insulated rocks, and is traversed by the Sitten, a brook which springs from an adjacent glacier. The town is tolerably well built and contains a cathedral, an Episcopal palace, a town-house, a public school, six churches, and several monasteries. On the highest of the rocks above mentioned, called Tourbillon, stand the ruins of the old Episcopal palace. On the second rock, called Valeria, stand the remains of the old cathedral, and a few houses, in which the canons reside; the third rock, Mayoria, is occupied by the Episcopal palace, an ancient stone building, erected in 1547. In one of its apartments the diet assembles, and in the other the bishop holds his court. Population 5000. East Long. 7° 9', North Lat. 46° 11.

SIR JAMES LANCASTER'S SOUND, an immense inlet opening from Baffin's Bay at N. Lat. 74°, and about 30 minutes of Long. W. from the meridian of Washington City. This Sound, the existence of which was long doubted, has been recently explored and made memorable in geographical discovery by Captain Parry, of the British navy, who entered it in 1820, penetrated to Melville Island, and ascertained its existence as far West as 117° W. from Greenwich, or 40 W. from Washington City. Reduced to English statute miles, Sir James Lancaster's Sound is determined eight hundred miles from Baffin's Bay, and gives precision to the geography and hydrography of the earth in those Arctic regions. Commencing with Cape Farewell, the separation of North America and Greenland is shown upwards of 2000 miles. Hearne, McKenzie, and Franklin, have found the open northern ocean, at N. Lat. 68, and 69°. The discoveries of Hearne and Franklin, have placed the termination of North America, directly south, 7 degrees of latitude from Melville Island. The mouth of the Unjigah is, according to our best maps, at N. Lat. 69°. The discoveries of the British and Russians, when combined, leave uncertain but a small portion of the northern coast of North America, and prove two very important facts in Geography, the existence of a Polar continent, or very extensive group of islands, and the slight connexion, if not entire separation of America and Greenland.

DARBY.

---

* See Dr. Brewster's *Journal of Science* No. XV. p. 61.

SIRENE.—The Sirene, an instrument for measuring the number of vibrations of the air, which are required to produce a sound, was invented by Baron Cagniard de la Tour. It was made on the principle that if, as is the general opinion, the sound of instruments is produced by the regular impulses given to the air, by their vibrations, then any mechanical means of striking the air with the same regularity and velocity should also produce sound.

The invention is as follows: A current of air is passed from a bellows by a small orifice, which is covered by a circular plate, moving on a centre, at a little distance on the side of the aperture. Through this plate there is bored a certain number of oblique holes in a circle round the axis, which passes over the orifice of the bellows; and the holes are placed at equal distances from one another. When the plate is made to turn round, which, owing to the holes being oblique, may be easily done by the current of air itself, or by mechanical force, the aperture is alternately open and shut to the passage of the air, by which means a regular succession of blows is given to the outward air, and produces sound similar to the human voice, and varying in the degree of acuteness, according to the velocity of the plate.

In the instrument, in place of one aperture, there are many, which are opened and closed at the same time, by which means its strength is increased, without the height of the sound being at all interfered with. The instrument is a circular copper box, four inches in diameter, having its upper surface perforated with a hundred oblique holes, each a quarter of a line wide, and two lines in length; there is an axis upon which the circular plate moves, on the centre of this surface; this plate is also pierced with 100 holes, similar to those below, and equally oblique, but lying in a contrary direction. The circumstance of their being oblique is not necessary to produce sound, but it gives motion to the plate by the passing air. The connexion between the box and the bellows that supplies with air, is effected by means of a tube.

In the experiments made for the purpose of ascertaining the vibrations for each sound, the revolution of the plate was accomplished by wheel work, set in motion by a weight: the bellows were then put in action only to judge whether the sounds of the instrument agreed with the notes of the harmonica, which consists of an arrangement of iron or steel bars, made to vibrate by a bow.

Thus constructed, the instrument was made to produce the diatonic notes of the gamut, and even some beyond them: the revolutions of the plate were estimated by the revolutions of a wheel, which turned with a velocity of thirteen times and a half less than that of the plate.

The following table is the result of these experiments; but the inventor of the instrument intends to refine and improve his machinery, and then repeat and extend them.

Notes.	No. of revolutions made by the wheel in 1′.	No. of revolutions made by the plate in 1″.	No. of vibrations produced in 1′.
la	19	$4\frac{27}{100}$	427
si	$21\frac{1}{4}$	$4\frac{77}{100}$	477
ut	$22\frac{3}{4}$	$5\frac{11}{100}$	511
re	25	$5\frac{67}{100}$	567
mi	28	$6\frac{30}{100}$	630
fa	30	$6\frac{75}{100}$	675
sol	34	$7\frac{65}{100}$	765
la	38	$8\frac{55}{100}$	855
si	$42\frac{1}{2}$	$9\frac{55}{100}$	955
ut	$45\frac{1}{2}$	$10\frac{23}{100}$	1023
re	50	$11\frac{25}{100}$	1125

The first la corresponds to the second of the harmonica, and is the unison of the common diapason.

If water is passed into the Sirene in place of air, sound is produced, even though the instrument be entirely immersed; and the same number of concussions produces the same sound as in the air. It was owing to this circumstance of the instrument being sonorous in water, that it has acquired the name of Sirene.

The instrument now described is nearly the same as one invented by the late Dr. Robison and described in his *System of Mechanical Philosophy*, vol. iv. p. 405. The following is the passage which contains it.

It seems to be the general property of sounds that a certain frequency of the sonorus undulations gives a determined and unalterable musical note. The writer of this article has verified this by many experiments. He finds that *any noise whatever*, if repeated 240 times in a second, at equal intervals, produces the note C *sol fa ut* of the guidonian gamut. If it be repeated 360 times, it produces the G *sol re ut, &c.* It was imagined that only certain regular agitations of the air, such as are produced by the tremor or vibration of elastic bodies, are fitted for exciting in us the sensation of a musical note. But he found, by the most distinct experiments, that any noise whatever, created the same effect, if repeated with due frequency, not less than 30 or 40 times in a second. Nothing surely can have less pretension to the name of musical sound than the solitary snap which a quill makes when drawn from one tooth of a comb to another: but when the quill is held to the teeth of a wheel whirling at such a rate that 720 teeth pass under it in a second, the sound of G *in alt* is heard most distinctly; and if the rate of the wheel's motion be varied in any proportion, the noise made by the quill is mixed, in the most distinct manner, with the musical note corresponding to the frequency of the snaps. The *kind* of the original noise determines the kind of the continuous sound produced by it, making it harsh and fretful, or smooth and mellow, according as the original noise is abrupt or gradual; but even the most abrupt noise produces a tolerably smooth sound when sufficiently frequent. Nothing can be more abrupt than the snap now mentioned, yet the *g* produced by it has the smoothness of a bird's chirrip. An experiment was made of a sound which was less promising than any that can be thought of. A stopcock was so constructed that it opened and shut the passage through a pipe 720 times in a second. This apparatus was fitted to the pipe of a conduit leading from the bellows to the wind chest of an organ. The air was allowed to pass gently along this pipe by the opening of the cock. When this was repeated 720 times in a second, the sound *g in elt* was most smoothly uttered, equal in sweetness to a clear female voice. When the frequency was reduced to 360, the sound was that of a clear but rather harsh man's voice. The cock was now altered in such a manner that it never shut the hole entirely, but left about one-third of it open. When this was repeated 720 times in a second, the sound was uncommonly smooth and sweet. When reduced to 360, the sound was more mellow than any man's voice at the same pitch. Various changes were made in the form of the cock, with the intention of rendering the primitive noise more analogous to that produced by a vibrating string. Sounds were produced which were pleasant in the extreme. The intelligent reader will see here an opening made to great additions to practical music, and the means of producing musical sounds, of which we have at present scarcely any conception; and this manner of producing them is attended with the peculiar advantage, that an instrument so constructed can never go out of tune in the smallest degree. See the *Annales de Chim. et de Phys.* vol. xii. p. 167, and Robison's *System of Mechanical Philosophy*, vol. iv. p. 403—405.

SITTINGBOURNE, a small town of England, in the county of Kent. It forms chiefly one wide street, extending along the high road, which here descends towards the east. The church, which is the principal public building, is a spacious edifice, with a nave, two aisles, a chancel, two chapels, and a tower at its west end. With the exception of the tower, the whole has been rebuilt since 1762, when it was destroyed by fire. There is a curious monument in the north or Bayford chapel, having in its recess the emaciated figure of a female in a winding sheet. There are here many urns, some of which are very elegant and commodious. In 1821 the town and parish contained 294 houses, 325 families, 269 families employed in trades, and 1,537 inhabitants. See *Beauties of England and Wales*, vol. viii. 697.

SIVAS, anciently Cabira or *Sebaste*, a large town of Asiatic Turkey, and capital of a government of the same name. It is situated on the great river Kizil Irmak, near its source, and on the north side of a plain which it traverses. There are two stone bridges about a mile distant. The town is dirty and ill built, being composed of wood, roofed with masses of stone and clay. In the middle of the town are some extensive gardens, and on an artificial hill is an old castle falling into ruins. Some of the public buildings are said to be elegant, and some of the monuments lofty. There is a celebrated Armenian monastery not far from the town. Numbers of horses are reared in the vicinity, and corn is grown in great abundance in the valley. The size and population of the town is said to equal Liverpool. See Jackson's *Journey from India*.

SIUT, Assiout, supposed to be the ancient *Lycopolis*, is a large city of Upper Egypt. It stands on an artificial eminence about half a mile from the Nile, with which it communicates by a canal, crossed by a bridge of three arches. It is a well built town, and is copiously supplied with water. In the mountain above the city there are several spacious caverns, in one of which, hewn out of a free stone rock, there are three chambers, one 60 by 30, another 60 by 26, and a third 26 by 25. Caverns still more spacious occur farther up the mountain. The caverns are carved with hieroglyphics and emblematical figures. The Soudan caravans pass through this town, and form its chief support. Fine flax grows in great quantities in the neighbourhood. Flax and wheat are exported to Upper and Lower Egypt, and salt and other goods are brought back in exchange. Population about 25,000. East Long. 31° 38'. North Lat. 27° 25'.

SIWAH, or Siouah, a town and an oasis in the Libyan desert, celebrated as being the most probable site of the temple of Jupiter Ammon. Hornemann represents the valley as fifty miles in circumference, and Brown, as six miles long and four broad. The town is situated upon and around a mass of rock, in the subterranean caverns of which the ancient inhabitants are said to have resided. The houses still have the appearance of caves, and are huddled together in such close confusion that many of them have no light, and a stranger requires a guide to conduct him through the labyrinth. It is said to resemble a beehive, from its dense population and the confused hum which it emits. The territory is said to furnish about 1500 men capable of bearing arms. From being on the great caravan route, it is a place of considerable trade, many of the inhabitants being employed in the conveyance of goods between Egypt and Fezzan.

From the fertility of this territory, in the middle of an extended desert, and the catacombs in the neighbouring mountains, Siwah has been thought to be the site of the temple of Jupiter Ammon. Accordingly, there occurs a few miles to the westward a remarkable mass of ruins, called by the natives Ummebeda, and the original purpose of which cannot now be discovered. In the middle of a space enclosed by a wall about 900 feet in circumference, are found the ruins of what seems to have been the principal edifice. It is about 30 feet long, 27 feet high, and 24 wide. The walls are six feet thick, and the roof consists of large blocks of stone cemented together with small stones and lime.

There is no sculpture on the exterior of the walls, but in the interior are three rows of emblematical figures, apparently designed for a procession, and the space between them is filled with hieroglyphics. In some places even the colours remain. One of the springs near this building is sometimes cold and sometimes warm. After the rains, the ground in the vicinity of Siwah is for many weeks covered with salt.

SKELETON. See Anatomy, Index.

SKIDDAW. See Cumberland.

SKIPTON, a market town of England, in the West Riding of Yorkshire, is situated in the middle of a fertile vale of the same name. It consists principally of one long and wide street, and the houses are built of stone. The church, which stands at the end of the main street, is a spacious building, with a tower at the west end, and seems to have been rebuilt in 1655. The other buildings are a new town-house, and a grammar school, which has a good library. Skipton castle, a little to the east of the church, is said to have been erected soon after the conquest. Its works and defences were destroyed in 1646. Skipton is a great mart for grain, and great quantities of cattle and sheep are sold at its numerous fairs. There are here a paper mill and a cotton manufactory. The Leeds and Liverpool canal passes close by the town, and has numerous warehouses and wharfs on its banks.

In 1821, the township of Skipton contained 667 inhabited houses, 684 families; 462 families employed in trade, and 3411 inhabitants. See the *Beauties of England and Wales*, vol. xvi. p. 723.

SKY, Isle of, from *Ski*, which expresses mist or clouds in the Scandinavian language, the second largest of the Hebrides, or Western Isles of Scotland, is separated from the main land by various channels, the narrowest of which is less than one third of a mile in breadth. Its form is extremely irregular. Its greatest length is 45 miles, and its breadth from 10 to 24 miles. It occupies 342,000 English acres, of which about 30,000 are arable. It is deeply indented with inlets of the sea, so regularly distributed, that there is no spot of the island more than four miles from salt water.

The shores of this island, excepting at the bottom of the bay, are extremely rocky, and in the north-east and north-west, the coast sometimes rises to a height of more than 700 feet. In its general aspect the island is extremely mountainous. Blaven, the highest mountain in Sky, exceeds 3000 feet in height, and the mountain ranges vary in height from 1500 to 2500. Some of these hills are remarkable for the dark blue tints which they reflect, while others present a deeply indented outline, and inaccessible and overhanging peaks.

The principal sea lakes, or arms of the sea, are, Loch Oransa, Loch Ainort, Loch Portree, Loch Snizort, Loch Fallart, Loch Braccadale, Loch Harport, Loch Eynort, Loch Brittle, Loch Scavig, and Loch Eishert. The fresh water lakes, which are few in number, are, Loch Cornisk, Loch Creich, Loch Columb Kill, and Loch Shiant, or the Sacred Lake. The vallies are watered with rapid streams, which scarcely deserve the name of rivers. That which issues from Loch Correisk is the longest, but the largest are those which fall into Lochs Snizort and Portree, the principal of which is the water of Snizort, and the rivulets which issue from Loch Fud and Loch Leatha, the last of which forms a fine cascade at its exit from the lake. A stream near Loch Staffin falls into the sea through a height of 300 feet. The rivers abound in trout and salmon, and in the small rivers Kilmartin and Ord, is found the great horse muscle, in which pearls occur.

The climate of Sky is very wet, and scarcely three days out of twelve are free from rain. The clouds attracted by the hills sometimes break in useful and refreshing showers, and at other times burst in water-spouts, which deluge the plains and destroy the crops. Stormy winds, too, set in about the end of August and the beginning of September, and often greatly injure the standing corn. The temperature of the Island corresponds with its latitude. It is, however, very variable, like the Scottish climate in general, and about the end of winter and early in spring the air is cold and sharp. The prevailing diseases are agues, fevers, rheumatisms, and dysenteries. The people, are, however, healthy, for in 1821 there were in the parish of Sleat a woman upwards of 100, and in that of Portree *two* men and *five* women upwards of 100, and in that of Duirinish *one* male and *three* females.

The Island belongs to the county of Inverness. It is divided into seven parishes, whose population in 1821 was as follows:

	Houses.	Families.	Families in Trade.	Population in 1821.
Braccadale	375	376	18	2103
Duirinish	669	707	53	4147
Kilmuir	624	638	40	3387
Portree	530	555	21	3174
Sleat	459	476	37	2608
Snizort	525	534	32	2789
Strath	462	472	21	2619
Total	3644	3758	222	20,827

The presbytery of Sky includes, besides the above parish, that called the Small Isles, which is mostly in Argyllshire. The king is the patron of all these livings. The two principal proprietors are Lord Macdonald and Macleod of Macleod, the former of whom possesses three-fourths of the island, principally in its east end. The estate of Macleod occupies the N. W. portion. Strathard belongs to Mr. Macalister, and Macleod of Rasy owns a small track near Portree.

The principal towns or villages are Portree, the capital of the island, Stein, Kylehaven, and Broadford.

There is in Sky every variety of soil, except pure sand. In the district of Trotternish there are 4000 acres of loam, and loam and clay upon a gravelly bottom. In Sleat and Strath, and in Macleod's country, are extensive tracts of light friable mould upon gravel, and likewise some loam mixed with peat earth, well adapted for the established rotation of crops. The crops usually cultivated are beans, oats, potatoes, and some flax. Artificial grasses and hemp have been lately introduced. The grain raised in good years is estimated at about 10,000 bolls. The live stock of Sky is reckoned to be 4000 horses, of a small but hardy breed; 18,000 head of cattle of an excellent breed, of which about 3800 are exported annually. The sheep are estimated at about 40,000, consisting chiefly of the Cheviots and the black-faced Lintons. Hogs, goats, and rabbits abound, and game of all kinds is plentiful.

There are many ancient forts and monuments of a Druidical character in this island, various cairns and stones. At Struan, on the top of a rock, are the remains of a circular fort, 42 feet in diameter. The romantic castle of Dunvegan, the seat of Macleod, situated on a high rock at the bottom of Loch Fallart bay, forms two sides of a small square, and on the third side there is a Danish tower. The walls are, in two places, about seventeen feet thick. Between Dunvegan and Talisker are the remains of a massy wall, and the vestiges of a ditch encircling a precipitous rock, accessible only on one side; and on the summit of another adjacent rock is a Danish inclosure of a circular form, consisting of strong masonry without cement. The diameter of the inside is forty-two feet, and within it are vestiges of five small circular apartments. The entrance, which is covered with flags, is six feet high, and the walls of the inclosure are considerably higher. There are two large cairns about two miles to the north of this.

Duntuilm castle, or the castle of the large grassy eminence, was originally a seat of the Macdonalds. It stands on a lofty precipice near the north end of the island. Though in ruins, it is still in tolerable preservation. The remains of the castle of Dunscaich, the poetical residence of Cucullin, is boldly situated on an insulated rock, which a drawbridge connects with the shore. The ruins of the castle of Knock stand on the opposite side. The huge cairn of Bencallfach is said to have been erected over the grave of a Norwegian princess.

The geology of this island is exceedingly interesting, but even the briefest notice of it would exceed the limits of an article like this. In our article SCOTLAND, we have already given a general view of it in relation to the rest of the kingdom.* Many fine groups of basaltic columns occur on the island. In the parish of Snizort there is a perpendicular obelisk about 360 feet round at its base, and about 300 feet high, and on the same side of the parish there is a fine cataract about 90 feet high, with an arched hollow path in the middle across the rock, through which five or six persons can walk abreast. The *Spar Cave*, one of the greatest geological curiosities in the island, has been already fully described in our article GROTTO.

Many beautiful and even rare minerals are found in Sky, viz. perfect crystals of analcime at Talisker, chabasie in the rocks of the Storr; stilbite, mesotype, madelstein, laumonite, apophyllite, hyperstene, actynolite, and steatite.†

Sky is particularly distinguished, not only in Scotland, but perhaps in the world, for its grand and romantic scenery. Every part of its coast and finely indented shores abounds with scenes of unrivalled beauty and grandeur. Among these the most singular is Loch Scavaig and Loch Coruisk. The former is a narrow lake, encircled by rocky mountains dipping into the sea, and variegated with numerous isles of rock. From this we pass on a sudden into the sequestered lake of Coruisk, which occupies a glen about four miles long and half a mile wide, walled in with tremendous rocks of bleak and desolate grandeur. The lake, with its verdant isles, is about three miles long. All is here dreary silence and gloomy sublimity.

Sky is the country of caves: one of those in Strathaird sheltered prince Charles. Another in Loch Braccadale, disappointed Dr. Johnson. For farther information respecting this interesting island, see Johnson's *Tour to the Hebrides*, 1775. Martin's *Description of the Western Islands*. Dr. Anderson's *Account of the Hebrides*. Macdonald's *Survey of the Hebrides*. Macculloch's *Description of the Western Islands*. Macculloch's *Letters on the Highlands*, 1824.

SLATE. See MINERALOGY, Index.

SLAVE LAKE, if correctly delineated in Tanner's map of North America, is the third if not the second most extensive body of fresh water on this planet. The two great sources of the Unjigah appear to rise from the eastern slope of the Chippewayan mountains, and flow to the north-east. The most southern stream, Elk river, after a course of eight hundred miles, enters the western end of Athapescow lake, from which it again issues, and immediately below the outlet receives the Unjigah, an equal if not superior volume of water. The united stream, marked as Slave river, between N. Lat. 58° 30′ and 61° 30′, flows NNW., and expands in the great body of Slave Lake. The position and extension of this recipient is from NE. by E. to SW. by W. 350 miles, with a very unequal, but mean width of about 40 miles. From its extreme western angle issues Mackenzie's river, or more correctly the Unjigah river. The body of Slave Lake extends from 33° to 42° W. from Washington City, 1400 miles NW. from Lake Superior, and very nearly equi-distant, 700 miles from the Pacific Ocean and Hudsou's Bay.

DARBY.

SLAVE TRADE, is the name given to that commerce in slaves carried on principally between Africa and the West India Islands. This trade was begun by the Portuguese about the year 1481, when they established their first fort at D'Elmina. The other nations in Europe gradually followed the example, and a system was established by which the chiefs of the African tribes doomed their prisoners of war and their convicts to everlasting servitude, and exchanged them for the luxuries of European commerce. As the West India Islands advanced in prosperity, the demand for slaves increased. Speculators and adventurers from every part of Europe carried to the coast of Africa the alluring articles of their respective manufactures. Thus tempted on all sides, the African tyrants resolved to use every practicable method of obtaining slaves. War was excited for the purpose of taking prisoners. The innocent were charged with crimes which they never committed. The helpless were seized by violence, and the inhabitants of their own villages were sometimes carried off in a body to supply the means for the inhuman barter.

The victims thus seized are marched like cattle in droves to the river side or to the sea coast. They are coupled two and two by the neck with pieces of wood, or by other contrivances. Some are loaded with their provisions or with articles of trade for the masters. The weak must keep up with the strong, and the old must proceed at the same pace with the young.

When they reach the coast purchasers innumerable appear on all sides. The sale commences and the slaves when purchased are conveyed to their respective ships. The men are confined together two and two by fetters of iron, and put into the fore part of the vessel, the women occupy the after part, and the boys the middle. These apartments are grated at top for the admission of light. In good weather they are brought upon deck for air. They are ranged in a row on each side of the ship, and a long chain passes through the fetters of each pair to secure them to the side of the ship. After their meals, which consist of horse beans, rice and yams, with a little water, oil and pepper, they are forced to jump as high as their shackles will permit to the beat of the drum. When the cargo is made up, the ship weighs anchor, and the horrors of the *middle passage* commence.

The slave vessels vary from 12 to 800 tons, and carry from 30 to 1500 slaves. The height of the apartments varies from three to six feet, so that in some it is impossible to stand erect, and in others to sit down. In the best ships each person has scarcely as much room as a man has in his coffin. Lying on the bare boards, suffocated by the heat and moisture exhaled from themselves, excoriated by the rolling of the vessel, and immured in the filth of their lair, death is often

* The fullest details on this subject will be found in Dr. Macculloch's work on the Western Islands of Scotland.
† See our article SCOTLAND, for a list of Scottish minerals, in which the localities of the above species will be found

the least evil which befalls them. Some destroy themselves, and others seek revenge against their oppressors.

In this condition the blood-freighted vessel reaches its destined harbour. Wafted into the peaceful bay of a tropical shore teeming with the luxuriance of animal and vegetable life, it floats its living cargo among scenes of purity and peace. Here the slaves are prepared for sale. Sometimes they are disposed of to the highest bidder by public auction, and sometimes by a process called the "scramble." For this purpose the main and quarter decks are covered with sails, and the slaves are brought out into the gloomy area. The purchasers at a signal rush in among them with long ropes, and endeavour to enclose as many of them as possible. On some occasions the scramble is held on shore in an apartment or court yard, at the doors of which the purchasers are let in in a similar manner. The terror of the poor Africans is beyond description. The women cling to each other, and some of them have been known to expire with fear. Friends are here separated for ever. The father parts from his child, and the expressions of affection which often accompany the act of separation, are checked and even punished by the merciless purchasers.

About one fourth of the slaves shipped on the African coast expire during the passage; and during the first ten years of their servitude in the West Indies, which is called the period of seasoning, nearly the same number perish. From these two causes the annual loss of negroes was computed to be 45,000. The treatment of the slaves in the West India islands varies with the character of the proprietor; but there can be no doubt that in general it was severe and harsh, and in some instances marked with a brutality incompatible with the usages of civilized life.

Such is a brief view of that traffic which long stained the character of enlightened Europe. Many philanthropists raised their voice in favour of the unhappy Africans;—many politicians attempted to remove the stain from their country, and many Christians wept over the thought that such crimes could be tolerated in a Christian land. The miseries of the poor Africans were sung by our poets, were declaimed upon by our orators, and even discussed by our sages; but neither the song, nor the declamation, nor the argument mitigated their destiny. It was reserved for a band of men,—of Christian men,—entrenched in the strongholds of their faith, pure in their patriotism, and firm in their purpose, to free their religion and their country from the reproach of partaking in the odious crime. The men who took the leading part in bringing about this moral revolution, were Mr. Granville Sharpe, Mr. Thomas Clarkson, and Mr. Wilberforce, aided by many wise, and pious, and honourable men, whose names we cannot undertake to enumerate.* The active and persevering mind which gave life and motion to every combination, and which carried through even the drudgery of its details, was that of Mr. Clarkson, a man whom Providence seems to have endowed with all the qualities which were demanded for so difficult a work. The most deep-rooted prejudices everywhere beset his progress. The sophistry of metaphysics arrayed all its subtleties against the cause. The sordid views of self interest brought into the field still more formidable antagonists; but the most alarming enemy of all was the apathy and indifference of the nation. All these difficulties he contrived to surmount. He unmasked the man of syllogisms in his quibbles. The speculator he arrested behind his counter, and with the hand of Prometheus he put life into the inert mass of the people.

It would be interesting to trace in detail the steps by which these grand objects were effected; but our limits will not permit us: and the subject is perhaps more suited to a chapter in the life of Mr. Clarkson, when it shall please Providence to call him to his reward. A rapid notice however will be expected by our readers.

When Dr. Peckard became vice-chancellor of the university of Cambridge in 1785, he gave out as the subject of the bachelor's prize, "*Anne liceat invitos in servitutem dare?* Is it right to enslave others against their will?" Mr. Clarkson, who had gained the bachelor's prize of the preceding year, gained also this. His mind was turned to the subject, and at the age of twenty-four he resolved to devote himself to the cause of the negroes. His Prize Essay be was induced to publish in an enlarged form, under the title of "An Essay on the Slavery and Commerce of the Human Species, particularly the Africans," which was honoured with the first prize in the university of Cambridge for the year 1785. The judicious and extensive distribution of this book made the great cause generally known; and Mr. Clarkson began with zeal to devote himself to the arduous labours which he had undertaken. By conversing with those who had been in Africa and the West Indies—by visiting the slave ships in the Thames—by an extensive correspondence with persons in Liverpool, and by repeated intercourse with members of parliament, he made himself master of the details of his subject, and he interested influential persons in his cause, by the information he communicated to them. Among those who entered most ardently into his views was Mr. Wilberforce, one of the members for Yorkshire, who pledged himself to bring forward the measure of abolition in the House of Commons, and who used his influence and his talents in every way in which they could be subservient to Mr. Clarkson's views.

A committee of zealous and good men was formed on the 22d May 1787, to carry through the abolition of the African slave trade. Mr. Clarkson now drew up a "Summary View of the Slave Trade, and of the probable consequences of its abolition." This little work of about twelve pages, containing the substance of the question, was circulated throughout the kingdom, and Mr. Clarkson set out on a journey to collect evidence and new information. About 100 petitions to parliament were presented by those who favoured the abolition; and, in consequence of Mr. Wilberforce's severe illness, Mr. Pitt introduced the question into the House of Commons, on the 9th May 1788, by a motion "that this House will early next session take into consideration the circumstances of the slave trade complained of in the petition, and what may be fit to be done thereupon." Pursuing the same views, Sir William Dolben, on the 21st May, brought in a bill

* It is due to historical truth to state, that the society of Friends took a most active and benevolent interest in this great work. As individuals and as a body, they have done honour to their species, and exalted themselves in the estimation even of those who differed most from them on speculative points in religion and politics.

for regulating the number of slaves to be carried by the tonnage of the vessel. This bill, after a warm opposition, passed both Houses, and received the royal assent on the 11th of July.

Having gained these preliminary points, Mr. Clarkson and the committee were roused to new exertions. Above 50,000 pamphlets were circulated, and much fresh evidence procured. On the 19th March 1789, Mr. Wilberforce moved the House to consider its own resolution of last session. This motion was agreed to; but it seemed only to rouse all the passions and interests which it affected. An opposition of the most tremendous character was excited, and such was the cry which was raised against the motion, against the characters of the abolitionists, that many well-wishers of the cause began to waver in their opinions. Mr. Wilberforce's motion was, on a motion of Mr. Pitt's, postponed till the 12th May, when Mr. Wilberforce, in a speech of three and a half hours, introduced the question into parliament, and laid down twelve leading propositions. These lay on the table till the 21st May, when the opponents of the measure insisted upon bringing forward evidence against it. In this way they gained time, and from the slowness with which they adduced their evidence, the question was postponed to next session.

In order to get the better of these dilatory measures, Mr. Wilberforce carried a motion that the witnesses should be examined in a committee room. The opponents of the measure closed their case, and that of the abolitionists came to be heard. Mr. Clarkson, who had been in Paris pleading the cause among the leaders of the French revolution, and who had been on board every ship of war at our naval stations to collect witnesses, now arranged his evidence for the House of Commons. Twenty-five witnesses were examined this session, and forty-five gave their evidence at the beginning of the next. The revolution in St. Domingo, however, and an insurrection in Dominica, furnished the anti-abolitionists with plausible arguments. The complete emancipation of the slaves, the indemnification of the planters, the massacre of the whites, and the total ruin of our colonies, were held forth as the immediate consequences of abolition. These circumstances produced a powerful effect, and notwithstanding the powerful, and eloquent, and argumentative appeal of Mr. Wilberforce, on the 18th April 1791, the question was lost by 163 votes against 88. This minority was graced with the names of Pitt, Fox, Burke, Grey, Sheridan, Wyndham, Whitbread, and Francis; and mortifying as the defeat was, it served perhaps to advance the cause, by enlisting on its side the feelings of the great body of the people, and by giving the committee an opportunity of unmasking the specious pleas of their opponents, and placing in their true light the imaginary horrors which had been held out as the legitimate consequences of the abolition.

In June 1791, Mr. Clarkson undertook to abridge the evidence taken before parliament. It was printed in September, and in order that it might be perused by the people, he followed his book through the island; he employed influential individuals to peruse it, and lend it out to others, and with the aid of Mr. William Dickson, a zealous ally, he completed his arduous task.

By the end of March 1792, no fewer than 517 petitions against the slave trade were laid before parliament. On the 2nd of April, Mr. Wilberforce moved that the African slave trade be abolished. The house agreed to its *gradual abolition*, but various divisions took place both then and on the 23d and the 25th of the same month, on the question whether it should terminate in 1793, 1795, or 1800. Both 1793 and 1795 were rejected; but the intermediate year of 1796 was preferred to 1800, by a majority of 151 to 132.

It now came to the House of Lords, where evidence was again heard, and the matter postponed to next session.

In 1793, Mr. Wilberforce again moved the Commons on the subject; but his motion was lost by a majority of 61 against 53. In May, he again moved for a bill to abolish that part of the trade by which British merchants supplied foreigners with slaves. This motion was carried by a majority of seven, but the bill was lost on the third reading by a majority of 31 to 29.

Thus defeated on all hands, the abolitionists were thrown into a state of inconceivable perplexity. Vexation and disappointment had begun to affect even the powerful mind of Mr. Clarkson. His bodily frame now gave way, and he nearly lost his memory, his hearing, and even his powers of articulation. Mr. Wilberforce, however, still kept the field, and tried the question in 1796, 1798, and 1799, but he could gain nothing but the acknowledgment of the principle of abolition in a limited time. The year 1800, 1801, 1802, and 1803 were allowed to pass without any new application to parliament; but in 1804, after the union with Ireland, which added to the House of Commons several warm friends of abolition, Mr. Wilberforce resumed his motion of abolition in a limited time, which was carried by very considerable majorities. When taken up to the Lords, however, it was postponed to next session.

In 1805, Mr. Wilberforce's renewed motion was actually lost by a majority of 77 to 70; but this defeat, severe as it was, was compensated by the re-appearance of Mr. Clarkson at his post. The cause had declined with his health, and was again destined to revive under his management. The death of Mr. Pitt in January 1806, led to the formation of a new ministry under Mr. Fox and Lord Grenville, who, to a certain degree, took up the question of abolition as a cabinet measure. With this view the Attorney-General brought in a bill to prohibit British merchants and British capital from being employed in the foreign slave trade. This bill passed both Houses, and in the debate which took place, both Lord Grenville and Mr. Fox declared that they would exert themselves to effect the abolition of the slave trade, and that they would consider their success as adding more glory to their administration than any other measure which they could pass. Mr. Fox accordingly, on the 10th June, moved "that this House, considering the African slave trade to be contrary to the principles of humanity, justice, and policy, will, with all practicable expedition, take effectual measures for the abolition of it in such manner, and at such a period as may be deemed most advisable." This motion was carried by 114 against 15. Mr. Wilberforce then moved an address to his Majesty, praying him "to direct a negotiation to be entered into by which foreign powers should be invited to co-operate with his Majesty in measures to be adopted for the abolition of the African slave trade." This was carried without a division.

The resolutions and the address were submitted to the House of Lords, on the 24th June, by Lord Grenville in a speech of great power. They were both carried by a majority of 41 against 20. It was now generally believed that the slave trade would be abolished during the next session; and therefore it was feared that the merchants would avail themselves of this last year to carry on the trade to a tenfold extent. Another bill was therefore introduced and carried, to prevent any new vessel from going to the coast of Africa for slaves.

The session of 1807 was not far advanced when the subject was again introduced. Lord Grenville thought it expedient to introduce it into the House of Lords under the name of an act for the abolition of the African slave trade. It was presented on the 2d January. Four counsel were heard against it on the 4th, and on the 6th, after a brilliant debate, it was carried at six in the morning by a majority of 100 to 36. On the 10th January, it was brought before the Commons; on the 20th counsel was heard against it; and on the 23d January, upon the motion of Lord Howick (Earl Grey,) it was carried by the triumphant majority of 283 to 16. After the blanks were filled up, it again passed both Houses, and received the royal assent on the 25th January 1807, a day memorable in the annals of humanity.

SLEAFORD, New, a market town of England, in Lincolnshire, is agreeably situated on the Slea. The place is flourishing, and has a handsome Gothic church, with a tower and spire 144 feet high. It has a free school, and a hospital for twelve poor men. Population of the town and parish in 1821 about 2220. See *Beauties of England*, vol. ix. p. 758.

SLESWICK, or South Jutland, is a province of Denmark. It occupies 3600 square miles, and has a population of 300,000 on the mainland, and 40,000 on the islands. The chief towns are

	Population.
Flensborg	15,000
Kiel	7,000
Sleswick	7,000
Tondern	2,600
Tonningen	2,000

See our articles Denmark, and Kiel.

SLESWICK, the capital of the above province, is agreeably situated on the river, or Gulf of Sley. It is very long, and irregularly built. The houses are of brick, and resemble, in their neatness and general aspect, those of the Dutch. The principal buildings are the cathedral, five churches, the town-house, the orphan house, the work-house, and the nunnery of St. John. There is here a refinery of sugar, and manufactories of leather, earthen ware, and sail cloth. The Sley is now navigable by means of a canal. The old palace of Gottorp, which is a large brick building, encircled with a rampart and moat, stands close to the town. East Lon. 9° 35′. North Lat. 54° 32′.

SLIDE is the name given to an inclined plane for facilitating the descent of heavy bodies by the force of gravity. In general, they have been objects of no great importance; but one was lately erected at Alpnach, in Switzerland, which has excited great interest throughout Europe.

For many ages, the craggy sides and the deep ravines of Pilatus, a lofty mountain near Lucerne, were thickly clothed with vast and impenetrable forests of spruce fir, of the largest size, and the finest quality, surrounded on every side by the most terrific precipices, inaccessible to all but a few daring hunters, who, at the risk of their lives, scaled these precipitous rocks and crags, in pursuit of the chamois. It was from these bold adventurers that the first intelligence was derived concerning the size of the trees, and the extent of the forests, until a foreigner, who had visited their sequestered glades and gloomy recesses, in pursuit of the chamois, was struck with amazement at the sight, and pointed out to the attention of several Swiss gentlemen, the vast extent, and superior quality of the timber. The project of making use of these rich natural stores, was however rejected as chimerical by persons, whose experience and skill made them competent to judge; and it was consequently abandoned. This attempt having failed, these immense and valuable forests would, in all probability, have been suffered to flourish and decay, without ever being applied to the use of man, if it had not been for the enterprising genius, and the unwearied exertion of M. Rupp, a native of Wirtemberg, who, owing to some political changes which had taken place in his own country, had settled near the Lake of Lucerne. His curiosity being strongly excited by the accounts he had heard of the forest, he was induced to visit it. He was so much struck by its wonderful appearance, that he entertained the idea of being able to convey the trees into the Lake of Lucerne, solely by their own gravity. During his long residence in Switzerland, his character and talents were so much appreciated, that, with the assistance of three Swiss gentlemen, he soon formed a company from among the proprietors, with a joint stock, to enable them to purchase the forest, and to construct a road or *Slide*, down which it was intended the trees should be precipitated in the Lake of Lucerne, an arm of which washed the bottom of the mountain, from which they could be easily conveyed by the Rhine to any part of the German Ocean. This stupendous undertaking was finished in 1816.

The Slide of Alpnach was composed of between 25,000 and 30,000 large pine trees, squared by the axe, and formed into a sort of trough, about six feet broad, and from three to six feet deep. In the bottom of the trough there was a groove for the reception of a small stream of water, let in over the side of the trough every now and then, in order to keep the whole structure moist, and thereby to diminish the excessive friction, occasioned by the rapidity of the descent of the tree.

The slide was sustained by cross timbers, and these cross timbers were themselves supported by uprights fixed into the ground. It was sometimes carried along the faces of the most rocky eminences, sometimes it went under ground, and again it crossed the deepest ravines, where it was supported by scaffoldings 120 feet high. The skill and ingenuity which were displayed, and the difficulties which were surmounted, in this vast undertaking, gained a just tribute of admiration to the enterprising individual who projected and carried it through. Before the work could even be begun, it was necessary to cut down many thousand trees, to obtain a passage for the labourers through the impassable thickets. And M. Rupp was himself frequently obliged to descend the steepest precipices, suspended by ropes, at the imminent hazard of his life. And though he was attacked by a violent fever, yet his ardour was so great that he had himself conveyed every day, on a barrow, to the mountain, in order to superintend the operations of his workmen. The expense attending this undertaking was, according to one account, £9,000 or £10,000; but according to another only £4,250. Before the trees were launched into the slide some previous preparation was necessary, which consisted in lopping off the branches, and stripping them of the bark, that they might descend with the greater ease. Every thing being prepared, the tree was introduced into the trough, with the root foremost; and it descended with such velocity as to reach the lake in 6 minutes, a distance of about three leagues or nine miles; but the largest trees performed the same distance in about three minutes. In order to prevent the accidents, which might take place, if the tree was let off before every thing was ready at the lower end, a regular telegraphic communication was established between the two extremities of the slide; and workmen were posted at regular distances, of about a mile from each other, and so arranged that every station should be visible from the ones both above and below it. When the tree was launched the workmen at the upper end hoisted their telegraph, (which consisted of a board, turning at its middle on a horizontal axle. The board when placed upright was visible from the two stations above and below it, but when it was turned horizontally it was not perceptible from either,) the same signal was repeated by all the rest in succession, so that the workmen at the lower end of the trough received intimation of the approach of the tree almost instantaneously. In a few minutes the tree came thundering past the men, and plunged into the lake. The lowest board was then turned down, which was followed immediately by all the rest, and thus the workmen at the top were informed of the safe descent of the tree. The same operation was repeated during the rest of the day; and it was so arranged that a tree should descend every five or six minutes. When the progress of the tree was impeded by any obstacle, or when it started out of the trough, the board was only half depressed; and as the workmen knew by this signal that something was wrong, those who occupied the stations above and below the place where the tree had stuck, came and assisted in removing the obstruction, which was generally occasioned by the springing of a beam in the trough.

In order to prove the enormous force which the trees acquired by the rapidity of their descent, M. Rupp caused some of them to spring from the trough. The result was, that they penetrated the earth by their thickest ends to the depth of 18 and sometimes 24 feet. And one of them having accidentally come in contact with another, cleft it from top to bottom with the violence and rapidity of lightning. In order that none of the small wood might be lost, M. Rupp constructed several extensive manufactories in different parts of the forest, for the purpose of reducing it to charcoal. He also built magazines for preserving it when made. The trees, after having reached the lake, were made up into rafts, and floated down the Reuss by the Aar, into the Rhine. By this rapid conveyance, they generally arrived at Basle a few days after they had left Lucerne. At Basle they passed out of the hands of the company. They were still floated down the Rhine in rafts to Holland; and thus performed a journey of about 4000 miles in less than a month from the time they left Pilatus, until they arrived at the German Ocean.

We are sorry to add that this stupendous work of art is now totally destroyed; and that almost every trace of it is obliterated on Mount Pilatus. The great demand which formerly existed for the timber having entirely ceased, owing to political causes, the cutting and transporting of the timber was necessarily discontinued, and the slide was suffered to go to ruin. See Playfair's *Works*, vol. i. Appendix, No. 2, p. 89.

SLIDING RULE. See Arithmetic, where we have given a drawing and description of this useful instrument. In the Philosophical Transactions for 1815, p. 9—29, Dr. Roget has published a "description of a new instrument for performing the involution and evolution of numbers," in which will be found many useful observations and improvements on the sliding rule. An account of it will be found in the Supplement to this work, together with a description of Dr. Young's improved sliding rule for gauging casks. See Brande's *Journal*, vol. xvi. p. 367.

SLIGO, a county of Ireland, in the province of Connaught, is bounded on the east by Leitrim, on the south by Roscommon, on the south-west and west by Mayo, and on the north by Donegal Bay. Its greatest length from north to south, from Bunduff to the Curlew mountains, is 39½ miles, its greatest breadth 38, and its area 465,280 English acres. It contains six baronies and 39 parishes, and sends to parliament three members. About a third part of this county is occupied with bogs, mountains, and lakes. The best part of it is to the south of Sligo, where the county is fertile and beautiful, there being about 140 square miles where the soil is suited for grazing or tillage. In other places a good deal of the soil is shallow and moorish, lying above what is called *lea-clea* or grey flag. The waste land lies principally in the north and west.

The principal streams are the Sligo, Bonnet, Owenmore, Arva, Cooloney, Esky, and Moy, which separates the county for several miles from Sligo. The Sligo, which flows out of Lough Gill, is navigable to Sligo, and the Moy is navigable for six or seven miles from the sea.

The chief fresh water lakes are Lough Gill, Arva, Talt, and Gara. Lough Gill, which possesses some charming scenery, has a number of wooded islands, on one of which, viz. Innismore, are the ruins of a church, and the remains of other buildings. Lough Arva is about eight miles long, covered with islands, and irregular in its form. The Arva flows out of it northward to Ballysadere, and throws itself in a stupendous cataract into the ocean. The chief bays are those of Killala and Sligo, which communicates with Lough Gill. The island of Innismurry lies to the north of Sligo Bay. There are salmon fisheries of considerable importance on the Sligo and the Moy. Trout abounds in the Talt and Gara, and white fish is found plentifully on the coast.

The principal minerals in Sligo are iron, which has for some years been wrought, lead, manganese, copper, and silver. There are strong indications of coal near Lough Gill, and there are various fine clays fit for pottery. Limestone, and limestone gravel abound, and also marl.

The estates in Sligo vary from £5000 to £9000 a year, and belong chiefly to absentees. The size of farms varies from three Irish acres to 500. The leases are for 36 years and three lives, and sometimes for 61 years and three lives. The chief articles of produce are oats, barley, and potatoes. Illicit distillation is carried on very generally. Cattle and sheep are reared to a considerable extent.

The principal articles of export are linen, salt, kelp, butter, and corn.

The principal places in this county are Sligo, and about 20 hamlets, at which fairs are held.

The state of the peasantry in Sligo is nearly as bad as in any part of Ireland, with respect to their labour, their food, and their clothing. In 1815 the price of labour was only 10d. a day, and 1s. 1d. in seed time and harvest.

The population of the county was about 60,000 in 1790; but in the last census, taken in 1821, it was 127,879. The catholics are to the protestants as 80 to 1; and in 1815 there were in the parish of Kilmactige 1200 catholic, and only ten protestant families. See Parlan's *Statistical Survey of Sligo*, 1802.

SLIGO, a seaport town of Ireland, and capital of the preceding county, is agreeably situated at the mouth of the river Sligo, where it falls into Sligo bay. The chief buildings are a court-house, a jail, barracks, an infirmary, and a charter-school, handsomely endowed by the family of Wynne, the patrons of the burgh. The castle of Sligo, now in ruins, was built in 1262. There was a monastery built about the same time, the ruins of which are of some magnitude. Three sides of the cloister, covered with an arched roof, still remain; the workmanship of the arches and pillars is extraordinary, and sculpture adorns some of the pillars. The great east window is beautiful, and the relievos on the high altar deserve notice. The nave is spacious, with a sort of gallery round it, supported by stone pillars.

The harbour of Sligo admits vessels of 200 tons close to the quay. The exports consist of large quantities of linen for the English market in a finished state, and also of salt, butter, and kelp. There is here a linen hall, and in the county there are many bleaching greens. The town is governed by a provost and a town clerk. The population is above 10,000. The town sends one member to parliament.

SLING. See ARMS.

SLIP, among shipbuilders is used to denote a place with a gradual slope on the banks of a river, suited for shipbuilding.

Mr. Thomas Morton, late shipbuilder, Leith, has given the same name to an apparatus for hauling vessels out of the water, in order to be repaired. This contrivance is a substitute for dry docks, and having erected it in his own building yard at Leith, and brought it to perfection by successive improvements, Mr. Morton secured the exclusive right to it by a patent.

Mr. Morton's slip is represented in section in Plate DII. Fig. 1, where A, B, C, are the sections of three railways, forming a plane, inclined at nearly the same angle, as the slips generally used by shipbuilders. This railway is placed on a sloping beach, and extends from above the reach of the tide down to low water mark. A carriage or frame of timber seen in section at D, E, F, G, H, runs along the iron railway upon rollers on truck wheels, guided by flanges. Blocks are laid upon the middle or keel beam E of the carriage to such a height, that the keel of the vessel may clear the ends of the cross pieces D and F, and each block embraces four trucks, two on each side of the beam. The blocks seen at M and N, which slide upon the cross pieces, are made up to suit the rising of the ship's bottom; they run out to the extremity of the cross pieces, and their ropes *r*, *s*, (*r* belonging to the left hand blocks, and *s* to the right hand ones) crossing the carriage, are reeved through a sheave attached to the opposite cross piece, up to the top of the rope rod. The shores S, S, (when any are necessary) are put into their places, turn upon a joint at T, and are prevented, when the vessel is floating on, from falling outwards by a small chain. Mr. Morton was at first in the practice of using shores; but having never found the slightest inconvenience or risk, even with vessels of the sharpest bottoms, many of which have been upon the slip, he has not of late found it necessary to use them, though they are particularly specified in his patent. He is still of opinion, however, that they may be useful when ships of war are brought upon it, for which, he is confident, it is well calculated.

In order to haul ships ashore, the carriage thus prepared is let down the inclined plane generally at low water. The chain of a powerful purchase is then attached to the carriage, and a waterstaff is placed at the fore end of the keel beam, to mark the depth of the water, and to be a guide in floating the vessel on. The vessel is then brought to the lower end of the carriage, and hauled over it, (having bow and quarter lines to steady her) till the advanced part of the keel takes the blocks between the fore foot guides. The ends of the ropes *r s* are now taken on board from the rods R R, but kept slack, and the vessel is hauled forward as the water flows, until the keel takes the blocks at the contracted part of the guides, which are just wide enough to receive it. Being still afloat abaft, having been previously so trimmed, the vessel is then adjusted over the blocks abaft by a water line. When the iron guides *a b*, *c d*, are hauled up by their ropes *a e*, *d f*, they confine her to settle down truly. By heaving the purchase, she will soon take the blocks abaft, which is observed by the water mark left upon her bottom. She is trimmed upright, and the foremost bilge, or sliding blocks, hauled in tight. As she rises out of the water, each succeeding block is hauled in, but not till the weight of the vessel has settled well on her keel; and the shores (if used) are brought to her sides, and there secured. Thus prepared, she is hauled up the inclined plane at the rate of from 2½ to 5 feet per minute, by six men to every hundred ton. When hauled up, she is shored from the ground; the keel beam is secured from moving; and the sliding blocks, with the cross pieces are, in a few minutes, removed, when the vessel is ready to be repaired.

The blocks being relieved of the vessel in the usual manner, the keel beam, with the after cross beam will run from under her. The carriage is again put together, and another vessel can be hauled up astern of the former. In point of fact, it is usual to have more than one vessel on the slip at the same time.

In launching a vessel, the cross pieces with their blocks are placed beneath her, and she immediately descends into the water. In order to launch and haul up vessels the same tide, temporary blocks are put under the bottom of the vessel to be launched, upon the cross pieces, instead of the sliding blocks which are prepared as before to suit the bottom of the vessel to be taken up. The vessel is then launched, and she and the temporary blocks which steadied her, float from the carriage. The other vessel is then taken on and hauled up as formerly described.

The advantages of this invention are numerous and important. It can be erected in situations where it is impracticable to have a dry dock, and at an expense which is comparatively inconsiderable; and it can be removed from one place to another, and may even be carried on board a ship, and applied to use on voyages of discovery and in remote situations, where repairs would otherwise be impracticable. The apparatus and the ship under repair being both above ground, the air has a free circulation; the men work with more comfort, and in winter they have the light much longer than within the walls of a dry dock. There is a saving of time in carrying the materials for repairing the ship; and such is the facility of the whole operation, that ships can be hauled up and inspected, and even get a trifling repair, and be launched again the same tide. As the mechanical power is attached solely to the carriage, the vessel is exposed to no strain, and the work of repair on one vessel is never interrupted by hauling on another, as in dry docks.

The whole expense of Mr. Morton's slip, exclusive of the cost of preparing the foundation and laying down, (which must vary according to circumstances) may be stated nearly as follows, viz.

For vessels of	100 tons	£450
	200	600
	300	800
	400	1000
	500	1100

and for vessels of greater burden in proportion.

An attempt was made about four years ago to invade Mr. Morton's patent; but his right was finally established by a court of law. On this occasion a number of witnesses were examined, including several officers of high rank in the royal navy, who all agreed that the slip was an invention of great practical utility; the naval officers being farther of opinion, that it might be made to answer for hauling ships of war out of water as well as mercantile vessels. The editor of this work has also seen the most satisfactory statements from a number of shipbuilders and others who have used the slip for several years, during which not a single accident has occurred in their practice, any more than in that of the patentee himself. It is now in use in many of the seaports of Great Britain and Ireland; slips have also been sent by Mr. Morton to France and Russia by the orders of the governments of these countries; and one, we understand, has been recently forwarded to Philadelphia.

With reference to the introduction of the slip into the United States of America, it may be mentioned, that within these three years an apparatus, meant to serve the same purpose, has been erected at New York by a native of Great Britain, all the valuable parts of which seem to have been taken from Mr. Morton's slip, with the addition of other contrivances of little or no utility, to give it the appearance of an original invention. The expense of this construction must have been several times that of Mr. Morton's. The apparatus laid down at Manhattan Island, understood to be for vessels of 400 or 500 tons, having cost, (but every thing included till it was ready for use,) nearly £17,000; and it does not appear to be calculated to receive more than one vessel at a time. We have looked into the documents containing these facts, and think it due to our country and our countrymen, that our transatlantic brethren should not be allowed the merit of an invention to which they have no just claim.

Such we conceive to be its importance to the mercantile interest, that we think it may be useful to mention some of the ports in different parts of the United Kingdom, where it may be seen in use, viz.

SLOANE, Sir Hans. See Botany.

SLUICE, Governor. See Hydrodynamics.

SLUICE, an account of several new and ingenious sluices invented by Mr. Thom of Rothsay, will be found in Dr. Brewster's *Journal of Science*, vol. ii. p. 100, 102, 288; vol. iii. p. 154, 155, 343: and vol. iv. p. 180. A drawing and description of the most important will appear in the Supplement to this work.

SLUSE, René Francis, an eminent Dutch mathematician, was born of a noble family at Vise, near Liege, in 1622. He filled the office of canon of St. Lambert in Liege, and abbot of Amaz, and grand chancellor to the bishop and prince of Liege. He died at Liege in 1685, in the 63d year of his age. Slusius was a man of great literary as well as mathematical attainments. His principal work is entitled *Mesolabium seu duæ mediæ prop. per circulum et ellipsin vel. hyp. infinitis modis exhibitæ*, Leod. 1659, the second edition of which appeared in 1668, with an addition on analysis and geometrical miscellanies. He was a fellow of the Royal Society, and published the following papers in the *Philosophical Transactions*.

1. A Short and Easy Method of Drawing Tangents to all Geometrical Curves.
2. Demonstration of the same.
3. On the Optic Angle of Alhazen. See Montucla's *Hist. des Mathematiques*, tom. ii. p. 66, 159, &c.

SMALL-Pox. See Inoculation.

SMEATON, John, a celebrated civil engineer, was the son of an attorney, and was born at Austhorpe, near Leeds, on the 28th May 1729. At a very early age he evinced a great passion for mechanical pursuits, and displayed much ingenuity in the formation of his tools, and in various pieces of mechanism which he constructed; but it does not appear that he had devoted his time to scientific pursuits till he had reached the period of full manhood.

In 1742 his father who was anxious that he should follow his own profession, took him to London, where he attended the courts in Westminster Hall; but finding that nature had intended him for other purposes, he addressed a memorial to his father, which obtained him permission to follow the bent of his own genius.

From this time Mr. Smeaton continued to reside in London, and about 1750 he established himself as a mathematical instrument maker, a profession which brought him in contact with the ingenious men in the metropolis, and from this time he seems to have devoted himself particularly to philosophical pursuits.

In the same year he communicated to the Royal Society an *Account of Dr. Knight's Improvement of the Mariner's Compass.* In 1752 he communicated to the same body three papers, viz. an account of *some improvements on the air pump:* a description of *an engine for raising water by fire, being an improvement on Savary's construction to render it capable of working itself. invented by M. de Moura of Portugal;* and *a description of a new tackle of pulleys.* In 1751 he had invented a *machine for measuring the way of a ship at sea*, and he made two voyages in company with Dr. Knight to try it, and also a compass which he had invented. This instrument he subsequently described in the *Philosophical Transactions* for 1754.

In the year 1753 Mr. Smeaton was admitted a member of the Royal Society. In 1754 he laid before them an account of his *New Pyrometer,** and in the same year he undertook a voyage to Holland and the Netherlands, to see the works of art which these countries contained. The inland navigation of Holland must have particularly occupied his attention, and it is probable that he henceforth resolved to devote himself to the profession of an engineer.

In December 1755, when the Eddystone lighthouse was destroyed by fire, the proprietors applied to Lord Macclesfield, the president of the Royal Society, to recommend a proper person to rebuild it. His lordship recommended Mr. Smeaton, who executed the work to the satisfaction of all parties.

A full account of all Mr. Smeaton's operations has already been given in our article LIGHTHOUSE.† Mr. Smeaton's own account of this great work appeared in a folio volume in 1791, and he is said to have remarked that this work cost him more trouble than the erection of the lighthouse itself.

So early as the years 1752 and 1753 he was occupied with *an Experimental Enquiry respecting the natural powers of water and wind to turn mills and other machines depending on circular motion.* This inquiry was carried on by means of working models of undershot, breast, overshot, and wind mills, and an account of it under the above title, was in 1759 laid before the Royal Society, who honoured it with the Copley medal. A full account of these experiments has been already given in our article HYDRODYNAMICS and in MECHANICS.

Notwithstanding the reputation which Mr. Smeaton derived from the Eddystone lighthouse, he does not appear to have been fully employed as an engineer even five years after its completion. In 1764 he was appointed one of the receivers of the Derwentwater estates, and in the discharge of this duty he made many improvements on the mills, and on the estates of Greenwich Hospital. In 1775, when his business as an engineer had greatly increased, he was desirous of resigning that appointment, but at the urgent entreaty of his friends he consented to continue two years longer.

In 1771 he and his friend Mr. Holmes became proprietors of the works for supplying Deptford with water; and on this occasion it is likely that he made those experiments on the friction of water in conduit pipes, and on the discharge of water through orifices, which were found among his papers, and which were first printed in our article HYDRODYNAMICS, through the kindness of Mr. John Farey.

In the construction of mills our author exhibited sagacity and practical talent, improved by theoretical knowledge. Descriptions and drawings of his overshot and breast wheels are given in our article Hydrodynamics. He erected also a steam-engine at Austhorpe, in order to determine the power of Newcomen's steam engine, upon which he made considerable improvements.

About the year 1785, when his health began to give way, Mr. Smeaton withdrew himself, as much as possible, from the cares of business, in order that he might complete his description of the Eddystone lighthouse and some other works. These he fortunately lived to finish; but when he was walking in his garden at Austhorpe, on the 16th September 1792, he was afflicted with a paralytic stroke, which cut him off on the 28th October 1792, in the 69th year of his age.

Mr. Smeaton was a man of plain and unassuming manners, which were enlivened by a considerable portion of the fervour of genius. In his domestic and social capacity he was affectionate, kind, and sincere, and an ardent and unsolicited patron of merit. Besides the works which we have already mentioned, he published the following papers in the Transactions.

On the Effects of Lengthening the Steeple and Church of Lestwithiel in Cornwall, Phil. Trans. 1757, p. 198.

Remarks on the different Temperatures of the Air at the Eddystone Lighthouse and at Plymouth. Id. 1758, p. 488.

On the Menstrual Parallax arising from the Mutual Gravitation of the Earth and Moon: its Influence on the Observation of the Sun and Planets, with a Method of Observing it. Id. 1768, p. 156.

Description of a New Method of Observing the Heavenly Bodies out of the Meridian. Id. 1768, p. 170.

Observations on a Solar Eclipse. Id. 1769, p. 286.

Description of a New Hygrometer. Id. 1771, p. 198.

An Experimental Examination of the Quantity and Proportion of Mechanical power necessary to be employed in giving different degrees of velocity to heavy bodies from a state of rest. Id. 1776, p. 450.

Observations on the Graduation of Astronomical Instruments: with an explanation of the Method invented by the late Mr. Henry Hindley of York, to divide circles into any given number of parts. Id. 1786, p. 1‡

* See our article on EXPANSION.

† The original models of this national work, and the piece of lead found in the stomach of the lighthouse keeper, were given by Mr. Smeaton, to the late Earl of Morton, at whose death lady Morton presented them to the Museum of the Royal Society of Edinburgh

‡ For an account of this valuable paper, by M. Troughton, see our article GRADUATION.

New Fundamental experiments on the Collision of Bodies. Id. 1782, p. 337.

Observations on the Right Ascension and Declination of Mercury out of the Meridian near his greatest elongation, September 1786, with an Equatorial Micrometer of his own invention and workmanship. Id. 1786 p. 318.

A volume of Mr. Smeaton's reports was published in 1797. Mr Smeaton had the merit of establishing the *Society of Civil Engineers* in 1771; but in consequence of his having received some improper treatment from one of its members, it was dissolved in 1792, by the mutual consent of the members. Another Society of Civil Engineers is now in full activity, under the auspices and presidency of our distinguished countryman, Mr. Telford.

Mr. Smeaton was invited, upon his own terms, by the Empress of Russia, to superintend the great projects which she had in contemplation. He resisted, however, all the inducements which were proposed; and the Princes Dashkoff, through whom the invitation was made, is said to have replied to his refusal. "Sir Robert Walpole was mistaken, and my sovereign has the misfortune to know that there is one man at least who has not his price."

At an early period of Mr. Smeaton's life, he met with a curious adventure, arising from his likeness to the poet Gay. When he was walking with Mrs. Smeaton at Ranelagh, he observed an elderly lady and gentleman fix their marked attention upon them. After some turns, the strangers stopped, and the lady addressing Mr. Smeaton, said, "Sir, I do not know you, but so strongly do you resemble my poor dear Gay, we must be acquainted: you shall go home and sup with us; and if the minds of the two men accord as much as their countenances, you will find two cheerful old folks who can love you well; and I think you can as well deserve it." The strangers were the Duke and Duchess of Queensberry. Mr. Smeaton accepted the invitation, and the friendship of the parties continued without interruption.

SMELTING. See Metallurgy.

SMITH, Adam, a celebrated Scottish moral and political philosopher, was born at Kirkaldy, in Fifeshire, on the 5th June 1723. He was the only child of Mr. Smith, comptroller of the customs in that town, and who had formerly been private secretary to the Earl of Loudon, when he was principal secretary of state for Scotland. His father died a few weeks after the birth of his son, whose constitution was long infirm and sickly. When he was only three years old, and on a visit to his uncle, Mr. Douglas of Strathenry, he was stolen by a party of tinkers; but in consequence of an active pursuit of the vagrants, he was rescued from them in Leslie Wood. From the grammar school of Kirkaldy he was sent, in 1737, to the College of Glasgow. In 1740, he went to Baliol College, Oxford, as an exhibitioner on Snell's foundation. At Glasgow, his principal studies were mathematics and natural philosophy; but the lectures of Dr. Hutcheson seem to have inspired him with that taste for moral and political sciences, which guided all his future inquiries.

After a residence of seven years at Oxford, he spent two years with his mother at Kirkaldy. He had been destined for the church of England; but his love of study induced him to settle in Scotland, in the expectation of one of those moderate appointments which our country offers to literary men.

In 1748, he delivered lectures on rhetoric and belles lettres at Edinburgh, under the patronage of Lord Kames, and about this time he seems to have obtained the acquaintance of David Hume and Lord Loughborough. In 1751, he was chosen professor of logic in Glasgow, and in the year following he was removed to the chair of moral philosophy. This important situation he filled for thirteen years. In 1755, Mr. Smith contributed a review of Dr. Johnson's Dictionary to the Edinburgh Review, which was begun in that year. In the year 1759, Mr. Smith published his *Theory of Moral Sentiments*, to the second edition of which he added a dissertation *On the Origin of Languages, and on the different genius of those which are original and compounded.*

Mr. Charles Townsend was so delighted with this work, that he invited Mr. Smith, about the end of 1763, to accompany the Duke of Buccleuch on his travels; and the liberal terms which were offered to him, and the strong desire he had of visiting the continent induced him to resign his professorship.

Early in 1764, the Duke and Mr. Smith set off for the continent. From Paris they went to Geneva, round by Thoulouse, and after their return to Paris in December 1765, they spent nearly a year in that capital, where he enjoyed the society of Turgot, Quesnay, Neckar, D'Alembert, Helvetius, and Marmontel. Mr. Smith returned to London with the Duke in October 1766.

The next ten years of Mr. Smith's life were spent chiefly at his mother's in Kirkaldy, with the exception of a few visits to Edinburgh and London: and his time seems to have been devoted to the composition of his *Inquiry into the Nature and Causes of the Wealth of Nations*, which appeared in 1779, and which extended the reputation of its author to every corner of Europe.

In the year 1778, Mr. Smith was appointed one of the commissioners of the customs in Scotland. He therefore removed with his aged mother to Edinburgh, where he spent the most of his time principally in the society of his literary friends. In 1787, he was elected rector of the university of Glasgow; but his constitution had now begun to give way, and his health and strength gradually declined till the period of his death, which took place in July 1790, and which arose from a chronic obstruction in the bowels. A few days before his death, he gave orders to destroy all his papers, excepting a fragment of a great work on the History of Astronomy. Mr. Smith never sat for his picture; but the medallion of Tassie gives a correct idea of his profile, and of his general expression. He bequeathed his library and the most of his property to his cousin, Mr. David Douglas, late Lord Reston, on whose education he had employed much of his leisure.

Those who wish to peruse a fuller account of the life and writings of this eminent individual, are referred to the admirable account of him by Mr. Dugald Stewart, published in the *Edinburgh Transactions*, vol. iii. p. 55. See also our article on Political Economy.

SMITH, Robert, LL.D. and D.D. celebrated as the author of a treatise on *Harmonies*, and of a *Complete System of Optics*. His early history is not recorded, but it appears that he was admitted A.B. in

1711, LL.D. in 1723, and S.T.P. by royal mandate in 1737. In 1716, he succeeded his cousin, the celebrated Cotes, as Plumian professor of natural philosophy at Cambridge; and in 1722, he published Cote's *Harmonia Mensurarum* with additions. In 1742, he succeeded Dr. Bentley as master of Trinity college, Cambridge. Having been tutor to the Duke of Cumberland, he was made master of mechanics to the king. In 1738, he published his *Complete System of Optics*, in four books, viz. a popular, a mathematical, a mechanical, and a philosophical treatise, 2 vols. 4to. It is dedicated to the right honourable Edward Walpole, and contains many original investigations and observations. In 1747, he edited a second edition of Cotes's *Hydrostatical and Pneumatical Lectures*, and in 1748, he published his *Harmonics*, of which a second edition, improved and enlarged, appeared in 1758. He died at Cambridge in 1768, in the 79th year of his age. He bequeathed two annual prizes of £25 to two commencing bachelors of arts who should be the greatest proficients in mathematics and natural philosophy. He left also £2000 for repairing Trinity College, and £2500 to the university. See Harmonics.

SMITH, one of the northern counties of Tennessee, bounded by Sumner county of Tennessee W., Wilson SW., Warren and White SE., Jackson E., and Allen and Monroe counties of Kentucky N. Length from north to south 36, mean width 15, and area 540 square miles. The surface is rather broken, with much excellent soil. Some of the sources of Big-Barren branch of Green river rise on its northern extremity and flow into Kentucky. Cumberland river is its principal stream, entering from the east, and with a curve to the southward, traverses the entire breadth of the county, receiving a large confluent, Caney Fork, near the middle, at the seat of justice, Carthage. Population, 1820, 17,580, or a fraction above 32 to the square mile. Central latitude 36° 23′ N. Long. W. from Washington City 8° 50′.

Darby.

SMOLENSKO, a town of Russia in Europe, and the capital of a government of the same name. It is situated on two hills, and on the intermediate valley, watered by the Dneiper which is here navigable. The part of the town on the right bank of the river is defended by a wall thirty feet high, fifteen thick, and about three-fourths of a mile in length. This wall, the lower part of which is of stone, and the upper part of brick, traces the course of the hills, and has towers at every angle. A ditch and a covered way, and some modern redoubts add greatly to its strength. The houses of the common people are chiefly built of wood, and are generally one story high. It is divided into two parts by a wide street paved with stone, but all the other streets are floored with planks.

It was at this town that the Russians in 1812 gave battle to the French, and were defeated; and on this occasion the town was bombarded and set on fire;* and it was here, on the retreat of the French, that part of the town was blown up, when they were compelled to fly from it by the Russians.

Since that time, so disastrous to Smolensko, a part of the town has been rebuilt in a good style, and the public buildings are now considerable. The principal edifices and establishments are twenty churches and chapels, two cathedrals, a Lutheran and a Catholic church, a gymnasium, a military and trades' school, a seminary for priests, a foundling hospital, and a consistory. The principal manufactures are those of linen, leather, hats, and soap; and a very active trade is carried on in corn, flax, hemp, timber, masts, planks, honey, wax, hides, hogs' bristles, and Siberian furs. Riga, Dantzic, and the Ukraine are the places with which the trade is carried on.

Population 12,000. East Long. 31° 56′ 36″. North Lat. 54° 50′.

SMOLENSKO, Government of. See Russia.

SMOLLETT, Tobias, an eminent Scottish novelist and poet, was the son of Archibald Smollett, the fourth son of Sir James Smollett of Bonhill. He was born at Dalquhurn, near Renton, in the parish of Cardross, Dumbartonshire, in 1721.

Smollett was educated at the parish school of Dumbarton, and he afterwards prosecuted his studies at the college of Glasgow with diligence and success. Here he contracted a fondness for the medical profession, and was apprenticed to Mr. John Gordon of that city. In this capacity he studied medicine and the belles lettres. He occasionally indulged in satirical effusions, not only against those who merited it, but against the more decent and respectable persons whom he knew, and his conversation has been described as a "string of epigrammatic sarcasms against one or other of the company." In the seventeenth year of his age he wrote a tragedy, called the *Regicide*, the subject of which was the assassination of James I. of Scotland.

In 1740, when his apprenticeship was finished, he set out for London to solicit employment in the army or navy, and to bring his tragedy upon the stage. Although the exertions of his friends could not recommend his play to the favour of the theatres, they procured for him the situation of surgeon's mate to one of the ships of the line that went out in the unfortunate expedition to Carthagena in 1741, under Admiral Vernon.† Disgusted with the navy, our author quitted the service in the West Indies, and resided for some time in Jamaica, where he became acquainted with Miss Lascelles, a beautiful woman, whom he afterwards married.

In 1746 he returned to London, and though a whig in politics, yet the love of his country predominated, and he expressed his feelings respecting the cruelties of the English troops during the rebellion, in a poem, entitled, the *Tears of Scotland*,—a poem written with elegance and spirit. In the same year he published his *Advice*, a Satire, an acrimonious attack upon several individuals of rank and fortune. In the same year he wrote an *Opera*, entitled *Alceste*, for Mr. Rich, manager of Covent Garden; but in consequence of a dispute, which exposed the manager to the shafts of his wit, it was neither acted nor printed.

* See our article France.

† Smollett afterwards gave an account of this expedition in *Roderick Random*, and one more circumstantial in the *Compendium of Voyages*, in 7 vols. 12mo. 1756.

In 1747 he published his *Reproof*, a Satire, being the second part of the *Advice*, continuing the same system of inveterate attack upon all the leading personages of the times. In the same year he married Miss Lascelles, who expected a portion of £3000 in West India property. Trusting to this expectation, he lived elegantly and hospitably; but being able to recover only a small part of the above sum, and that by means of expensive litigation, he got into serious pecuniary difficulties, which compelled him to have recourse to his pen.

He accordingly devoted his time to literature, and brought out in 1748 his *Adventures of Roderick Random*, in 2 vols. 12mo. a work which both bettered his pecuniary circumstances, and widely extended his reputation.

The tragedy of the *Regicide*, already mentioned, was published by subscription in 1749, and he derived from it considerable emolument. He went to Paris in 1750, and about this time he composed his *Adventures of Peregrine Pickle, with the Memoirs of a Lady of Quality*, which appeared in 1751 in 4 vols. This work is marked with broad humour, and great knowledge of the world. Real personages and real incidents are often described, as in Roderick Random, but the adventures, and frequently the language, were stained with an indelicacy and immorality that were highly reprehensible. The edition was quickly sold; another was bought up in Ireland; and the work was translated into French. Our author received, too, a very handsome sum for inserting in this novel the *Memoirs of Lady Vane*, which were furnished by herself, and which gave additional popularity to the work.

Notwithstanding the great success of Roderick Random and Peregrine Pickle, Smollett seems to have been anxious to quit the profession of an author. He obtained about this time the degree of M. D. probably from some foreign university, and he announced his intention to practise medicine, by a work entitled, *An Essay on the External Use of Water, in a Letter to Dr. ———, with particular Remarks upon the present method of using the Mineral Waters at Bath in Somersetshire, and a plan for rendering them more safe, agreeable, and efficacious*, 1752, 4to. In the practice of physic, however, he was not successful, and was compelled again to have recourse to his pen. In 1753 he published his *Adventures of Count Fathom*, in 2 vols. 12mo. but it was neither so ably written nor so popular as its predecessors.

Encouraged by a liberal subscription, Smollett published, in 1795, a new translation of *the History of the renowned Don Quixote, from the Spanish, &c. illustrated with 28 new copperplates*, in 2 vols. 4to. When this work was printed, he made a visit to Scotland, to visit his mother, who then resided at Scotston in Peeblesshire; and he took an opportunity of visiting various parts of his native country, particularly the vicinity of Glasgow, the scene of his early affections, where he spent two days with Dr. Moore, then an eminent surgeon in that city.

When he returned to London, he was induced to take the chief management of the *Critical Review*, a new literary Journal, which began in 1756 under the patronage of the tories, and in opposition to the *Monthly Review*, which had commenced in 1749. His next work was, *A Compendium of Authentic and Entertaining Voyages*, digested in a *Chronological Series*, in 7 vols. 12mo.

In 1757, when a stain had been left on the courage of England, our author wrote the *Reprisal, or the Tars of Old England*, an after-piece in two acts, intended to excite the national spirit. It was favourably received at Drury Lane, and is still a favourite on the stage.

Early in 1758, Smollett gave to the world his *Complete History of England, deduced from the descent of Julius Cæsar to the treaty of Aix la Chapelle in* 1748, in four vols. 4to. This work is said to have been composed and printed in fourteen months, a mental effort almost unrivalled. It was reprinted in the following year in eleven vols. 8vo. and the weekly sale was above 10,000.

When Sir John Mordaunt was tried for his unsuccessful expedition against Rochefort in 1757, some blame was cast upon Admiral Knowles, who defended himself in a pamphlet bearing his name. This pamphlet was reviewed in the Critical Review with such improper acrimony, that the Admiral prosecuted the printer for a libel. When sentence was about to be pronounced against the printer, Smollett avowed himself the author, and was sentenced to a fine of £100 and three months imprisonment. This spirited conduct on the part of our author was highly applauded, and he was visited in the King's Bench prison by many of the most distinguished characters of the day.

During his confinement he composed his *Adventures of Sir Lancelot Greaves*, which first appeared in detached portions in the monthly numbers of the *British Magazine* for 1760 and 1761, but it was afterwards published separately in two vols. in 1762. About this time he wrote the histories of *France, Italy* and *Germany*, for the modern part of the *Universal History;* and in 1761, 1762 and 1765, he published, in five volumes, his *Continuation of the History of England* down to 1765.

The unpopular administration of Lord Bute was naturally defended by Smollett, when he perceived that its unpopularity was in some measure owing to the premier being a Scotsman. For this purpose he established a weekly paper called the *Briton*, which gave rise to the *North Briton*, under the management of the celebrated Wilkes.

In 1763 our author had the misfortune to lose his only daughter, who died in the fifteenth year of her age, and left him in a state of hopeless despondency. The state of his own health, which too assiduous study had impaired, combined with this domestic calamity, induced him to quit England for a milder climate. He accordingly spent about two years in France and Italy, and on his return in 1766, he published his *Travels through France and Italy, containing Observations on Character, Customs, Religion, Government, &c.* with an account of the *Climate of Nice*, and a *Register of the Weather*, in 2 vols. 8vo.

Having arrived in Edinburgh in the beginning of 1776, and spent some time with his mother, he went to Glasgow and made a visit to his cousin Mr. Smollett of Bonhill. At this time he was distressed with rheumatism and an ulcer in his arm. He left Scotland in August without much change upon his health, and spent the winter in Bath. Here his ulcer assumed an alarming appearance, but by mercurial applications, and corrosive sublimate taken internally, a cure almost miraculous was quickly effected.

Thus restored to health, he resumed his laborious toils, and in 1767 he published his *History and Adventures of an Atom*, in two vols. 12mo., a political romance, supposed to be written in 1768, and displaying under *Japanese* names the different party men in Great Britain from 1756 to 1761.

A recurrence of his ill health induced Dr. Armstrong and his other friends to recommend a journey to Italy; and from the inadequacy of his pecuniary resources, they applied to government for the office of consul at Nice, Naples, or Leghorn. Even this paltry situation was refused by the government of Britain to one of the most distinguished of her citizens, though it was asked not as a promotion to administer to his luxuries, but as a medicine to preserve his life. The minister who thus dared to insult the sufferings of genius, and to bring discredit upon the character of his sovereign and his country, merits what he will receive, the indignation of future ages. The government who had refused this pittance to a man whose name will throw a lustre over England when oblivion has mercifully withdrawn theirs from execration, had been supported in office by his wit and argument, and the only blame which they could lay to his charge was, that he refused to degrade himself by the sacrifice of his independence.

The mental agonies of Smollett, already too severe for his delicate and susceptible frame, were deeply aggravated by this act of base ingratitude. Dr. Moore has justly observed, that many feel remorse in a fearful degree on their death-bed from the thought of dying rich; but that none feel it from the thought of dying poor. Smollett enjoyed at least this consolation when he set out for Italy in 1770. After a short residence at Leghorn he retired to Monte Nuovo, a romantic situation in its vicinity. Here he composed and published in 1776, his *Expedition of Humphry Clinker*, in three vols. 12mo. a work which met with high approbation, and is regarded as one of the best of his works. This was the last effort of his pen. His bodily strength gradually declined, and he died at his house near Leghorn on the 21st October 1771, in the 51st year of his age.

His widow erected a plain monument to his memory, with an inscription by Dr. Armstrong. In 1774 a Tuscan column was erected to his memory on the banks of the Leven by his cousin, James Smollett, Esq. of Bonhill, with an inscription partly written by Dr. Johnson, Professor G. Stuart, and Mr. Ramsay of Ochtertyre.

An edition of Smollett's works, in 8 vols. 8vo., was published in 1797, with Memoirs of his Life; to which is prefixed a *View of the Commencement and Progress of Romance*, by the celebrated Dr. Moore. Dr. Anderson had previously collected the poetical works of Smollett, which appeared with an excellent Memoir of his Life, in the works of the British Poets. The same learned editor published a new edition of his *Miscellaneous Works*, in 1796, and in 1803, he published in a separate volume, *The Life of Tobias Smollett, M. D. with Critical Observations on his Works*, which went through several editions. The following is Dr. Moore's estimate of Smollett's character:—

"The person of Dr. Smollett was stout and well-proportioned, his countenance engaging, his manner reserved, with a certain air of dignity that seemed to indicate that he was not unconscious of his own powers. He was of a disposition so humane and generous that he was ever ready to serve the unfortunate, and, on some occasions, to assist them beyond what his circumstances would justify. Though few could penetrate with more acuteness into character, yet none was more apt to overlook misconduct when attended with misfortune.

He lived in a hospitable manner, but he despised that hospitality which is founded on ostentation. He invited to his plain but plentiful table, the persons whose characters he esteemed, in whose conversation he delighted, and many for no other reason than because they stood in need of his countenance and protection. * * *

Free from vanity, Smollett had a considerable share of pride, and great sensibility; his passions were easily moved, and too impetuous when raised; he could not conceal his contempt of folly, his detestation of fraud, nor refrain from proclaiming his indignation against every instance of oppression. * * *

He was of an intrepid, independent, imprudent disposition, equally incapable of deceit and adulation, and more disposed to cultivate the acquaintance of those he could serve, than of those who could serve him. What wonder that a man of his character was not what is called successful in life."

SMUT. See Agriculture.

SMYRNA, a city and seaport of Natolia in Asia Minor, situated towards the northern part of a peninsula upon a long and winding gulf of the same name, which is capable of containing the largest navy in the world. The town is about four miles round. It presents a front of a mile long to the water, and when approached by sea, it resembles a capacious amphitheatre, with the ruins of an ancient castle crowning its summit. The interior of the city, however, disappoints the expectations thus raised. The streets are narrow, dirty, and ill-paved, and the bazaars are in no respect handsome. Two caravanserahs with quadrangles within have a showy appearance from the cupolas which cover them. The shops are arched over, and have a handsome appearance, notwithstanding the gloom which the houses wear; those along the shore have gardens attached to them, at the foot of which are summerhouses overhanging the sea. The castle of Smyrna, which was probably built by the Genoese, occupies a large hill at the east side of the city, and about three-fourths of a mile in circumference. There are no appearances of its having been very magnificent, the remains of a very thick and strong wall, being very like that which surrounded the city.

There is now scarcely a trace of those once splendid edifices which rendered Smyrna one of the finest cities of Asia Minor. The foundations of the theatre still appear on the slope of the hill. On the gateway of the castle is a fine, though mutilated colossal statue, supposed to be that of the Amazon Smyrna. There are marks of an extensive aqueduct, but its antiquity is doubted.

The river Meles which is here from 50 to 100 yards wide, waters an extensive and fertile plain behind the city, covered with numberless olive trees. This city is subject to earthquakes, and it has often suffered from the plague, which, in 1814, carried off above 50,000 of the inhabitants.

The bay of Smyrna affords excellent anchorage, and the water is so deep, that sloops of considerable burthen can anchor close to the wharf.

Smyrna carries on an extensive trade with Europe on the one hand, and Asia on the other. Of all the Asiatic nations the Armenians carry on the greatest trade with this city, and the caravans from Persia are principally composed of them. The European shipping regulate their motions by the periods at which these caravans arrive and depart, in order that they may supply the Asiatics with the merchandise of the west, and may reload their own vessels with the goods of Asia. The English carry on the greatest trade with Smyrna, and are most esteemed. The French trade is carried on chiefly from Marseilles, and the Italian trade from Leghorn. The exports from Smyrna are coffee, cotton, wool, camel and goat's hair, currants, wax, soap, pearls, and lapis lazuli, precious stones, opium, rhubarb, amber, musk, and gums. The imports from Europe are piastres, cloth, silken stuffs, paper, cochineal, argol, indigo, sugar, lead, tin, glass, spices, dyewoods, &c.

The whole town is a continual bazaar, abounding with the best commodities of Europe and Asia. In 1790, 1791, and 1792, the exports to London were £779,610, and the imports thence to Smyrna, £848,240.

The inhabitants of Smyrna are generally estimated at 100,000, and are composed as follows:—

Turks - - - - -	50,000
Greeks - - - - - -	30,000
Armenians - - - - -	15,000
Europeans - - - - -	5,000

The governor is appointed by the Porte. He decides the civil matters of the city; but in criminal cases he is subject to the cadi who is judge of the district. In the neighbourhood of Smyrna, there are some very fine villages, such as Bournabat, Cuklireiah, Bugiah, and Sadig, to which the more opulent inhabitants resort in summer. East Long. 27° 4′ 45″, North Lat. 38° 29′.

SNELLIUS, WILLEBROD. See OPTICS.

SNOW is the name given to the watery vapour in the upper region of the atmosphere, when frozen during its descent to the earth.

Snow is a congeries of an immense number of separate and transparent crystals of ice; and its whiteness is owing to the same cause as the whiteness of froth or of painted glass, namely, to the accumulated light which each separate crystal reflects to the eye of the observer.

The specific gravity or density of snow is very variable, as the following table will show.

		No. of inches of snow that yield one inch of water.
Sedileau	-	5½
De la Hire	-	5½
———	in 1710	12
Weidler	1728	9
Muschenbroek	1729	24* Utrecht.
Mr. Bryce	1766	10 Kirknewton in Scotland.
Mean of the above		11

When the snow falls during frost the flakes are always less, and they are greater when the air is warm. In July 1819, in the neighbourhood of Edinburgh, a slight shower of snow fell, in which the flakes were fully *two inches and a half* in length. Two or three years afterwards a similar fall was noticed in another part of Scotland.

Snow is occasionally found in North America in *balls* and in *cylinders.* On the 1st April 1815, Professor Cleaveland observed a great number of balls of snow from 1 to 15 inches in diameter, the small ones being nearly spherical, and the larger ones somewhat oval. Their texture was homogeneous, and they were extremely light, being composed of minute prisms of snow irregularly aggregated. These balls were formed by having been rolled through a considerable distance by the wind, their paths upon the snow being, in general, distinctly visible. The smaller balls, however, were decidedly formed in the atmosphere, as they occurred in woods and in small enclosures. See Professor Silliman's *Journal*, vol. vi. p. 169.

Cylinders of snow were first observed by the Rev. D. A. Clark in Morris county, New Jersey. When a deep snow was on the ground a shower of rain fell, and in consequence of a sudden cold the rain was congealed on the surface of the snow, and formed upon it a cake of ice. Another shower of snow fell to the depth of 3-4ths of an inch, and the sky having suddenly cleared, the cold became very intense, and the wind blew a gale. Nature, says M. Clark, now began her sport. Particles of snow would move upon the icy crust from 12 to 20 inches, and would then begin to roll, making a track upon the ice shaped like an isosceles triangle. The balls enlarged according to circumstances, and aided by the declivity of the ground, the rolls were of the size of a barrel, and some even larger. Thus the whole creation, as far as the eye could see, was covered with snow balls differing in size from that of a lady's muff, to two and a half or three feet in diameter, hollow at each end to almost the centre, and all *as true as so many logs of wood shaped in a lathe.*

In 1812 or 1813 Mr. Hitchcook observed at Deerfield, Massachusetts, similar cylinders of snow: none of them, however, were more than six or seven inches in diameter. See Professor Silliman's *Journal*, vol. ii. p. 132 and 375.

In the Arctic Regions, as Mr. Scoresby informs us, it snows *nine* days out of ten in the months of April, May, and June. With southerly winds near the borders of the ice, or where moist air blowing from the sea meets with a cold breeze from the ice, the heaviest falls of snow occur. In this case a depth of two or three inches sometimes falls in an hour. These heavy falls frequently precede sudden storms.

The crystals of snow present an endless variety of forms. Descartes and Dr. Hook seem to have been among the first who observed and delineated the

* This was what Muschenbroek calls starry snow, or that which was finely crystallized in the form of stars.

figures of the crystals.* Dr. Green and Dr. Langwell likewise observed them.† Dr. Stocke has delineated several beautiful forms of snow which fell at Middleburg in Zealand, in 1740 and 1742.‡ The most elegant delineations, however, of the particles of snow are those which were executed by Dr. Nettis of Middleburg, to the number of 80, and given in the *Philosophical Transactions*, 1755, p. 644, and those which were observed by Mr. Scoresby in the Polar seas, given in his "Account of the Arctic Regions," to the amount of 96. The general size of the particles which exhibit these regular figures, is from one-fifth to one-twentieth of an inch. We should have copied several of the figures given by Dr. Nettis, but we prefer taking those of Mr. Scoresby, because he has described the magnitude of each particle which he has delineated, and the state of the barometer, thermometer, and weather, at the time when it fell. Mr. Scoresby arranges the various modifications and crystals which he has observed under five kinds.

1. Lamellar. 2. A lamellar or spherical nucleus, with spinous ramifications in different places. 3. Fine spiculæ or six-sided prisms. 4. Hexagonal pyramids. 5. Spiculæ, having one or both extremities affixed to the centre of a lamellar crystal.

1. *Lamellar crystals.* Mr. Scoresby assures us that the varieties of this modification are very numerous, occurring abundantly at all temperatures, and being very thin and transparent, and of a highly delicate structure. These, he says, may be divided into several distinct species.

a. Stelliform; having six points radiating from a centre, with parallel collateral ramifications in the same plane. This species, represented in Plate CCCCLXXXVIII. Fig. 1. is the most general form met with. It varies in size from the smallest speck, to about one-third of an inch diameter. It occurs in greatest profusion when the temperature approaches the freezing point.

b. Regular hexagon. This occurs in moderate as well as in the lowest temperatures: but it becomes more delicate and thin, and diminishes in size as the cold increases. Some specimens consist of simple transparent plates, (Fig. 23.) others are beautifully variegated, within the perimeter, by white lines, forming smaller hexagons or other regular figures, in immense variety; Fig. 25, 27, 28, 30; Fig. 49, &c. The size of this species is from the smallest visible speck to about one-tenth of an inch diameter.

c. Aggregations of hexagons. This beautiful species admits of immense variety. It occurs chiefly at low temperatures, and presents great limits of dimensions: Figs. 2, 9, 10, 11, 17; and Figs. 29, 34, 37, 39, &c. afford examples of this species.

d. Combinations of hexagons, with radii or spines, and projecting angles. This constitutes the most extensive species in the arrangement: and affords some of the most beautiful specimens. Fig. 7, is an elegant combination of spines and hexagons; and Figures 50, 55, 58, 59, 60, &c. together with all the others distinguished by the letter *s* after the numbers, constitute a novel and beautiful variety, which I have only once observed. The parallel lines that appear in these figures, are not intended as shadings, but actually occurred in the crystals, though with this difference, that the lines which appear black in the plate, were all white in the originals. Figures 56, 63, 64, and 93, were opaque crystals, and were not so thin as the others.

The latter of these, as well as Fig. 94, each having twelve spines, appear to be accidental varieties, and are produced probably by the correct application of two similar crystals upon one another.

2. *A lamellar or spherical nucleus with spinous ramifications in different planes.*—This genus not being easily represented, is not illustrated by any figure. It consists of two or three species.

a. The fundamental figure, consisting of a lamellar crystal of any of the species above described, from the lateral and terminal planes of which arise small spines, similar to the collateral ramifications of Fig. 1. These spines arise either from one or both of the lateral planes or principal surfaces, or from both lateral and terminal planes; and always maintain the usual angle of 60° with the plane from which they take their rise.

The diameter of this figure sometimes exceeds the fourth of an inch. This species falls most frequently at a temperature of 20° or 25°.

b. Having a spherular nucleus, giving rise to radii in all directions. In the former species, the central figure is a transparent crystal; in this it consists of a small rough white concretion. The spines or radii are similar in both figures. The diameter of this seldom reaches a quarter of an inch. The form is echinose. This species falls when the degree of cold is near the freezing, and sometimes in rather low temperatures.

3. *Fine spiculæ or six-sided prisms.*—These are sometimes very delicate and crystalline; at others white and rough. The finest specimens, which resemble white hair cut into lengths not exceeding a quarter of an inch, are so small and clear, that the exact figure is not easily determined; and the larger exhibit a fibrous or prismatic structure. Some of these are occasionally the third of an inch in length. This genus is only seen when the temperature is near the freezing point. When the thermometer is about 28 degrees, the finer specimens occur; when about the freezing, the coarser appear. The latter are very common during fog showers, and appear to be composed of aggregations of the frozen particles of the fog, and to have their origin in the lower parts of the atmosphere.

4. *Hexagonal Pyramids.*—This kind of snow-crystal I have but once seen. A variety, consisting apparently of a triangular pyramid, was observed; but whether its base was a triangular or six-sided figure, similar to No. 95, is doubtful. These pyramids were about the thirtieth part of an inch in height, and fell along with some other curious figures, during a fresh gale of wind from the northward, in very large quantity. Figures 44, and 47, represent this kind of crystal.

5. *Spiculæ or prisms having one or both extremities inserted in the centre of a lamellar crystal.*—This is the most singular genus I have ever seen, and has been observed but twice. It resembles a pair of wheels, united by an axletree; the wheels consisting of hexagonal or other lamellar crystals, and the axle of a slen-

* *M[illegible]graphia*, p. 83, and Fig. 7—27. † *Phil. Trans.* 1693, No. 92. p. 5123. ‡ Muschenbrook's *Elem. of Nat. Phil.* Eng. Edit. vol. ii. p. [illegible]8, and Plate XXVI. and *Phil. Trans.* 1762, p. 112.

der prism. Fig. 43, 45, 46, and 48, represent this modification of snow-crystal. Fig. 46, consists of but one tabular crystal and a prism: and Fig. 45, of three laminæ and two prisms. The length of this was one-sixth of an inch: of the other kind, from one-thirtieth to one-tenth. Some of this extraordinary figure occurred along with the last-described genus: of which kinds, principally, a quantity of snow three or four inches in depth, once fell on the deck of the ship in which I sailed, in the course of a few hours. The temperature, when this kind of crystal fell, was in one instance 22°, and in the other 20°.

Plate CCCCLXXXVIII. contains representations of ninety-six different snow-crystals, magnified from thirty to about four hundred times. The Italic letter following the number of the figure, refers to the second column of the annexed Table, by which, the state of the atmosphere and weather, when each crystal was observed, may be seen. The fractional number which succeeds the Italic letter, shows the diameter of the crystal in parts of an inch. The largest crystal represented was one-third of an inch diameter; the smallest one-thirty-fifth. They were all perfect figures. Many instances, it may be observed, occur of mutilated and irregular specimens; some wanting two or three radii, and others having radii of different sizes and shapes. But in low temperatures, the greatest proportion of crystals that fall are probably perfect geometrical figures. This constant regard to equality in the form and size of the six radii of the stellates; the geometrical accuracy of the different parts of the hexagons; the beauty and precision of the internal lines of the compound figures, with the proper arrangement of any attendant ramifications, and the general completion of the regular figure,—compose one of the most interesting features in the Science of Crystallography.

A Table showing the State of the Atmosphere when each of the Figures of Snow delineated in Plate CCCCLXXXVIII. were observed.

Date.	Reference to the Parts	Thermometer.	Barometer.	WINDS.		REMARKS.
				Direction.	Force.	
1809, April 15	*a*	21	29.92	N.N.E.	Fresh gale	Snow very profuse.
17	*b*	19	29.84	N.N.E.	Fresh gale	A considerable quantity of snow.
29.	*c*	19	29.63	E.N.E.,N.N.E.	Light wind	Snow profuse.
May 1.	*d*	12	29.68	N.E.	Strong br.	Occasional crystals deposited.
2	*e*	10	29.84	N.N.E.	Fresh gale	Delicate crystals floating in the air.
3	*f*	18	29.87	N.E.erly	Strong gale	Snow in considerable quantity.
11	*g*	14	30.10	N.N.E.	Fresh br.	Profuse in quantity, accompanied by much opaque small gran snow
15.	*h*	22	29.78	E.	Strong gale	Ship's deck covered with these curious crystals, three or four inches deep.
30.	*i*	20	30.04	N.E.,N.	Fr. or str. ga.	Slight showers of snow.
June 16.	*k*	32	29.50	[Nearly	calm]	Fell in great quantities.
1810, April 12.	*l*	22	29.8[illegible]	E.N.E.	Strong gale	A constant light shower.
14	*m*	16	30.98	N.N.E.	Fresh br.	Small showers. Many rough crystals formed of opaque grains.
20	*n*	21	29.7[illegible]	S.erly	Strong gale	A moderate but continued deposition of snow.
21.	*o*	20	29.67	N.E.rly	Strong gale	Snow in considerable quantity.
May 16.	*p*	19	29.7[illegible]	N.	Brisk gale	Small showers; delicate crystals.
1816, April 29	*q*	23	29.95	N.N.W.	Mod. breeze	Small showers of fine crystals.
1817, May 2.	*r*	17	29.75	N.erly	Fresh gale	Showers of delicate well-formed crystals.
6.	*s*	27-26	29.80	S.E.	Fresh breeze	Various and beautiful figures vastly profuse; deck of the ship covered several inches deep.

The crystals thus described by Mr. Scoresby, and those delineated by Dr. Nettis, are obvious ice compound crystals: but they afford us no clue to determine the primitive form of the simple crystals of which they consist. This form has generally been supposed to be the rhombohedron: but Mr. Mohs and Mr. Haidinger maintain, "that there is not, in the whole compass of rhombohedral forms, an example of the same formation as the stars with six radii of snow, while it is common enough in those species which belong to the *prismatic* system." From Dr. Brewster's experiments on ice, (See our article on Ice.) it necessarily follows that the form of crystallized water must, as he has inferred, belong either to the *rhombohedail* or to the *pyramidal* system. The prismatic system being thus excluded, so far at least as ice is concerned, Mr. Haidinger considers the *pyramidal* form as the most probable one,* from the circumstance of *tin ore* and *rutile*, which belong to the pyramidal class, producing, by regular composition, crystallizations similar to the star-like figures of snow. That this is the case, has been put beyond a doubt by more recent observations by Dr. Brewster, made during the frost of the 18th and 19th November 1827, in which he found numerous and regular quadrangular plates, in the hoar frost, crystallized upon leaves and stones.

SNOW, Red, the name given to snow of a red colour, which was found by Captain Ross at Baffin's Bay on the 17th August 1819. The mountains that were dyed red with the snow were about eight miles long, and 600 feet high. The red colour reached to the ground in many places ten or twelve feet deep, and continued for a great length of time.

* *Edinburgh Journal of Science*, No. xii. p. 287.

Although the red snow had not previously excited much notice, yet it had been long before observed in Alpine countries. Saussure discovered it on Mount Breven in 1760, and on Mount St. Bernard in 1778. Ramond found it on the Pyrenees: and Sommerfeld discovered it in Norway. In 1818, red snow fell on the Italian Alps and Appennines. In March 1808, the whole country about Cadore, Belluno, and Feltri, was covered with a red-coloured snow, to the depth of six and a half feet; but as white snow had fallen both before and after it, the red formed a stratum in the middle of the white. At the same time, a similar fall took place on the mountains of the Valteline, Brescia, Carinthia, and Tyrol. Another fall of red snow is stated to have occurred between the 5th and 6th March 1803, at Tolmezza in the Frioul, and a still more remarkable one on the night of the 14th and 15th March 1813, in Calabria, Abruzzo in Tuscany, at Bologna, and over the whole chain of the Appennines. Red snow has also been found in New South Shetland.

Saussure had found that the colouring matter of the red snow was of vegetable origin, and he supposed it to be the farina of some plant. The Italian naturalists found in the red snow, clay, an oxide of iron, with a considerable portion of some organized substance; and M. Peschier of Geneva got the same ingredients in the red snow of Mount Bernard. Dr. Wollaston and M. Thenard obtained similar results.

The following is Mr. Peschier's analysis of red snow:

Siliceous matter,	65.5
Alumine,	6.35
Peroxide of iron,	21.35
Organized matter,	6.8
	100.0

In other specimens, the alumine was less, and in others there was none. In some there were traces of lime.

The botanists, however, have been more successful than the chemists. Mr. Bauer regarded the red matter as a fungus of the genus *uredo*, and called it *uredo nivalis*. M. R. Brown was of opinion that it had a great affinity to the *Tremella cruenta*, while *Sprengel* considered it as approaching near to the *Vaucheria radicata*.

In this state of the subject, Professor Agardh of Lund drew up a learned memoir on the subject, which is published in the *Nor. Act. Acad. Nat. Curios*, vol. xii. and of which a copious abstract has been published by Dr. Hooker in the *Edinburgh Journal of Science*, No. vii. p. 167-173. The conclusion to which he arrives is, that the red colouring matter "must either be an *alga*, or an *animalcula*, between which I know no certain limits. There are forms amongst them which may, with equal propriety, be ranked with either or both. There are *algæ*, which become *animalcules*, and *vice versa*. Lastly, there are *infusoria*, which, at one period of their existence, are endowed with the power of motion, while at another, they exist only in the state of a vegetable.

The colour of the red snow is not without analogy among the algæ. In autumn, there is produced on shaded walls a green powdery substance, composed of globules, which afterwards, according to circumstances, change either into *oscillatoria muralis*, or into *ulva crispa*. This substance comes nearest to *lepraria kermesina*. It has also a great affinity with *tremella cruenta*, (*Engl. Bot.*, and which must not be confounded with *ulva montana* of Lightfoot.) Both are red, and both consist of globules; but *lepraria kermesina* differs in this particular, that its globules are free, not sunk in a gelatine. I have accordingly placed *lepraria kermesina* of Wrangel in my *systema algarum*, as a peculiar genus, under the name of *proto-coccus kermesinus*." An account of Bauer's observations will be found in Brande's *Journal*, vol. vii. p. 222, 229; Peschier's Analysis will be found in the *Bibliotheque Universelle*, vol. xii. p. 266. See Saussure's *Voyages dans les Alpes*, tom. iii.

SNOW Blindness is a disease to which the inhabitants of the arctic regions are subject; though it sometimes occurs in more southern climates; it generally commences with a sensation similar to that of sand or dust getting into the eyes. A solution of acetate of lead is found to remove the complaint in two or three days; and its recurrence is prevented by defending the eyes either with a piece of crape, or a pair of snow spectacles. Xenophon informs us that many of the Greek soldiers were blinded by the brightness of the snow in crossing the snowy mountains of Armenia, between the Euphrates and Phesis, in the middle of winter; and he mentions, that they covered their eyes with something black.

The Greenlanders and Laplanders, who are especially subject to this disease, use a network of black horse hair, a little convex anteriorly. The Esquimaux on the coast of Labrador, use snow spectacles, which consist of a smooth piece of wood like poplar, which is driven on the Labrador coast. The back surface which covers the nose is pretty deeply cut. There is a notch at each side on the lower margin to give passage to the tears. The upper margin of the front projects to keep off the snow, and to act as a shade. The other side is blackened with soot. The apertures for vision are narrow, and slits are placed horizontally, so as to correspond to the opening of the eye-lids when nearly shut. These spectacles may be used with great advantage by persons with weak or inflamed eyes. This apparatus aids also the sight; and Ellis says, that the savages use it principally to see remote objects more distinctly.

For farther information on this subject, see Xenophon, *Cyrop.* iv. 5, p. 296, fourth edition of Hutchinson, *Cambr.* 1785. Kaud Leem, *on the Laplanders of Finmark*, p. 52. SNOWDON, is the name of a group of lofty mountains in Caernarvonshire. But the name is particularly applied to the highest mountain of the group, which, according to the results of the ordinance survey, is 3571 feet above the level of the sea, 3548.9 according to General Roy's barometrical observations, and 3546.25 according to Mr. Wollaston's thermometrical barometer. It is generally ascended by Llyn Cawellyn, half way between Bedgellas and Caernarvon. From the summit the view is grand and extensive. The mountains and part of the coast of Scotland, the county of Wicklow in Ireland, the Lancashire hills, the Westmoreland and Cumberland hills, with the Isle of Man, are all seen in the distance; while the intermediate country appears like a map to the observer. Camden says that Snowdon is covered with snow throughout the year: and though this is not the case at present, it might have been, and if we believe human testimony, must have been in his time. His words are, "It harbours snow continually, being throughout the year covered with it, or rather with a hardened crust of snow, and hence the British name of Craig Eryri, and the English one of Snowdon." Snowdon was held sacred by the ancient Britons, as Parnassus was among the Greeks, and it was said that whoever slept upon Snowdon would wake inspired. Leland informs us, that stags were found here in his time, and according to Pennant they were extirpated in 1626.

The following description of the summit of Snowdon is given by Pennant:

"The summit which, by way of pre-eminence, is called *Y Wyddfa*, or *the Conspicuous*, rises almost to a point, or at least there is but room for a circular wall of loose stones, within which travellers usually take their repast. The mountain from hence seems propped by four vast buttresses, between which are four deep *cwms* or hollows; each, excepting one, has one or more lakes lodged in its distant bottom. The nearest was *Fynnon Las* or the *Green Well*, lying immediately below us. Its waters appeared black and unfathomable, and the edges quite green. From thence is a succession of hollows, surrounded by lofty and rugged hills, the greatest part of whose sides are perfectly mural, and form the most magnificent amphitheatre in nature. The Wyddfa is on one side; Cribb-y-distill, with its serrated tops, on another; Crib-Gotch, a ridge of fiery redness, appears beneath the preceding; and opposite to it is the boundary called Lliweed. Another very singular support to this mountain is Y Clawdd Gotch, rising into a sharp ridge so narrow as not to afford breadth even for a path." Pennant's *Tour in Wales*, vol. ii. See the *Beauties of England and Wales*, vol. xvii. p. 411, &c.

SOAP Manufacture. The soap which is manufactured for domestic purposes is a combination of the fixed alkalies, with different kinds of fat or fixed oils.

The recent discoveries of M. Chevreul have thrown much light on the chemical nature of soap. The fats and fixed oils he has found to consist of two substances, one of which *stearine* from στεαρ, *suet*, is solid at common temperatures, while the other, *elaine* from ελαιον, *oil*, is fluid at ordinary temperatures. Suet, lard, and butter, contain a greater quantity of stearine than of elaine, whence arises their solidity; while the fixed oils contain a greater quantity of elaine, and are on that account fluid. If we press congealed fixed oil between folds of bibulous paper, the solid stearine will be obtained separate, and if we press the bibulous paper under water a substance is obtained, which is pure elaine.*

In the formation of soap the stearine and elaine disappear entirely, and are converted into *margaric acid, oleic acid, and glyceine.* These two acids combine with the alkali, and form soap.

The following processes will convey to the general reader a tolerable idea of the manufacture of the different kinds of soap.

1. *Process for making Hard White Soap from Oil.* This process is that of Macquer. *Two* parts of good Spanish soda, and *one* part of quicklime are boiled in a vessel with twelve times as much water. The ley thus formed is to be filtered and evaporated till a phial, which contains one ounce of water, holds one and three-eighths of an ounce of this concentrated ley. In a vessel of glass or earthenware a mixture is made of *one* part of this ley, with *two* of oil of olives, or oil of sweet almonds; and it is occasionally stirred with an iron spatula till it is thick and white. The ingredients gradually combine, and in seven or eight days a firm and very white soap is obtained.

2. *Process for making Pure White Soap from Tallow.* Mix with 200 gallons of ley ten cwt. of the best home melted tallow. Let the whole be melted with a moderate fire, and when it is disposed to boil over, damp the fire either with ashes or with a damper. At the end of two hours it may be drawn away, and the pan allowed to settle about two hours, when the ley may be drawn off. Two or three boilings may be given every day, and they must be continued day after day till the whole assume the appearance of a curdy mass. A little is then taken upon the fore finger; and if it squeezes into a thin, hard, clear scale by the pressure of the thumb, it is fit for finishing. If, on the contrary, it appear greasy, and stick to the finger, and is of a soft consistency, add more ley, and if this does not sufficiently harden it, it must be boiled another time. When it has become such as to squeeze into a scale it must get a good boiling, and the fire be then drawn. After being cooled down with two or three pails of ley, pump off the ley as clean as possible in about two hours. When this is done, add eight or ten pails of water, (each pail containing nine or ten English gallons.) Apply the fire, and when the water and soap are properly incorporated by constant stirring, take some from a boiling part, and having laid it on the handboard see if the ley runs from it. If it does, more water must be added, and the boiling continued. But if no ley runs from the soap, continue boiling for a short time longer, and then add a pail of a solution of one-third of salt in two-thirds of water. This will effect what is called *cutting up the pan*, or separating the soap from the water. When this is done withdraw the fire, let the whole stand for half an hour, and pump off the water, which will carry along with it the remainder of the alkaline ley of the former boiling. This is called the *first washing*; and if kelp ley has been used the water pumped off will have a bottle-green colour. Six or eight pails of water must soon be added, and when the whole is again boiled and incorporated, try if the water runs from the soap. If it does, add water in small quantities at a time, until the ley, when put upon the handboard, does not run down from the soap, but appears as it were just starting from the soap. When this is done give the whole a good boiling, and swell the soap up in the boiler to near its brim, and having withdrawn the fire, spread it about to die away.

The boiling process being now finished, the whole may stand twelve or fourteen hours, and if the quantity be two or three tons, it will be the better of stand-

* As the elaine requires a cold of 20° Fahrenheit to freeze it, it is peculiarly adapted for oiling the wheels of watches, &c.

ing double that time, keeping it however close and warm in the boiler. If any blueness remains, the washing must be repeated.

The frames into which it is now to be cast should have a bottom, and be lined with coarse cloth. If a perfume is wished for, a little of the essential oil of Caraway seeds, mixed with a small portion of alcohol, may be incorporated with the soap in putting it into the frames, stirring in a little of it at a time to diffuse it through the mass.

When it is cast into the frames, the whole should be covered up with old sheets, mats, &c. and allowed to cool gradually for three or four days, when it may be taken out, and cut into pieces of the required size.

2. *Process for making hard, brown, or yellow soap.*

In order to charge a pan for hard yellow soap, pour in 150 or 200 gallons of ley, and add 10 cwt. of tallow, and 93 cwt. of rosin broken into small lumps. The whole is now to be boiled and stirred, taking care always to damp the fire when the materials swell up. After two or three hours boiling, withdraw the fire, and allow the whole to stand four or six hours, when the weak ley is to be pumped off and fresh ley added. If it is wished to pump off sooner, a few parts of cold ley must be thrown in a short time after the fire is drawn. The whole is now to be boiled a second time for two or three hours, and the boilings continued day after day till the soap squeezes into a scale between the finger and thumb, as described in the preceding process. When this is effected, the pan is to be treated in the same way as in the process for white soap, *six* or *eight* parts of water being in this case put in, in place of eight or ten in the white soap. If we wish to give a beautiful colour to the soap by means of palm oil, put 20lbs. of the oil into the boiler, when the soap is considered to be finished, then after boiling for half an hour draw the fire, and allow the whole to stand for 48 hours, when it may be cast into the frames. If the frames are 30 inches deep, the soap may be cut in bars in about *three* days.

The following table has been given as showing the average proportions of the materials for yellow soap.

	cwt.	qr	lb.			cwt.	qr	lb.	
Tallow	13	0	11		Soap	13	0	25	independent of water.
Rosin	3	2	18						
Palm oil	1	2	0						
Barilla	6	2	14		Refuse of tallow, rosin, and palm oil.	5	3	4	
Potash	1	0	16						
Lime	5	0	9						
Soap	25	1	21	with its water.					

3. *Process for making black or green soft soap.*

The difference between hard and soft soap is, that in the former the whole of the ley is extracted, while in the latter the whole is retained, forming a compound body with the other materials. This soap is of two kinds, viz. *first crown soap*, made of *tallow*, *hogs' lard*, and *olive oil*: and *second crown soap*, made with *tallow* and *whale oil*.

1. *First crown soap.* For a charge of eighteen barrels take

	cwt.	qrs.
Tallow - - - - - -	2	2
Hogs' lard - - - - - -	2	2
Olive oil - - - - -	70 gallons.	
Ley from Hungarian ashes eight parts, and English ashes one part - -	400 gallons.	

When one-third of the ley, or 133 gallons, is put into the boiler, add the tallow, and after it is melted, put in the olive oil. Let the fire be now drawn a little, and the whole stand *two* hours. When the fire is again lighted, put in twenty gallons additional ley. As the whole boils, add occasionally a little more ley to prevent the soap from boiling over, until the soap is considered to be half boiled, when it will be time to ascertain whether the soap has got too much or too little ley. This operation, called *proving*, and which is requisite frequently, is thus performed: With a knife take up a piece of the soap, and if it turns white upon the knife, and falls from it in short pieces, too much ley has been put in, and consequently a little more olive oil must be added. But if it fall from the knife in long ropy pieces, an additional quantity of ley must be added. If, on the other hand, it is neither too white nor too ropy, but transparent, it neither needs oil nor ley. When it arrives at this state it may be put into the barrels or other vessels destined to hold it. After the second lighting of the fire, the boiling should be briskly kept up, and when the soap is nearly ready, it should boil slowly till it is put into the barrels.

2. *Second crown soft soap.* For this soap take,

Tallow - - -	280 lbs.
Whale oil - - - -	82 gallons.
Ley - - - -	140 gallons.

When 100 gallons of the ley are put into the boiler, add the tallow, and when it is melted, put in the whale oil and draw the fire. When the whole has stood two hours, light the fire and add twenty gallons of ley. Continue to boil briskly till the soap is considered to be half finished, and then put in ten gallons of additional ley. Add the other ten gallons during the rest of the boiling, and finish the soap as in the last process.

Hard soap in a proper state for the market, should contain thirty per cent. of water; but by fraudulent practices it may be made to contain sixty per cent.

The simplest and the most beautiful soap, is the fine white soap made of olive oil and soda obtained from the best barilla. A more expensive kind is made of soda and oil of sweet almonds. The former kind, which is made at Marseilles, Naples, and several parts of Italy, is sometimes streaked throughout with red and blue veins. This is effected by a solution of sulphate of iron, and by the brown red oxide of iron.

4. *Method of Improving Soap.*—Mr. Pope of Lombard Street, has given the following method of improving soap. Take one cwt. of good soap, slice it into thin pieces, and mix with it seven lbs. of marl of the purest kind, and a sufficient quantity of water, to reduce the whole into a fluid state. When the whole are stirred together till they are of the consistency of cream, they are boiled, and then poured out into suitable moulds for making them into cakes. By this process, the soap is rendered smooth and soft, and the action of the caustic alkali upon the skin is destroyed. See Dr. Brewster's *Journal of Science*, No. xiv. p. 361.

5. *Method of Making Transparent Soap.*—Put into a thin glass phial half a brick of Windsor soap, cut into small pieces; fill the phial half full of alcohol, and place it near the fire till the whole is dissolved. This mixture, put into a mould and boiled, is *transparent soap*. If well prepared, it should have the appearance of fine white sugar candy. It may be co-

loured; but vegetable colours should be used in preference to mineral ones.

Tallow soap is preferable, in making transparent soap, to olive oil soap, as the latter forms a paste too difficult to melt, and its odour too powerful for mixing with perfumes. Dr. Brewster's *Journal of Science*, No. xiii. p. 172.

Both the vegetable and the animal kingdom have supplied the inhabitants of different countries with a substitute for soap.

In America, the outer rhind of the seed of what is called the soap tree, is used by the natives; and in Africa, soap is made with a small insect of the carab genus. M. Geoffroy de Villeneuve, who a few years ago sent home some of this soap to Paris, gives the following account of it. "Being in the village of Portudal, a few leagues from Senegal, employed in collecting insects, and inviting the negroes to procure me supplies, one of them presented me with a pot, containing many thousands of a small insect of the carab genus. They were ready dried, and the numbers showed that they had been collected for some particular purpose. On inquiring, I learned that this insect entered into the composition of the soap used in the country. The same negro also showed me a ball of this soap, which was of a blackish colour, but had all the properties of our common soap; and I learned, in the sequel, that these insects are converted to the same purpose all along the coast of Senegal. This carab is black, but the edges or borders of the corslet, and also the elytres, are of a reddish colour; the feet and the antennæ are of a pale colour."

For farther information concerning soap, see *Experiences relatives a la Fabrication des Savons durs*, from M. Colin in the *Ann. de Chim.*, September 1816, vol. i. and a Memoir *on the Causes of the Diversities found in Soap, in reference to their hardness and smells*, in the *Ann. de Chim.*, *&c.* vol. xxiii. p. 16.

SOCIAL WAR. See Roman Empire.

SOCIETIES, Literary and Philosophical, are institutions established in the principal cities of all civilized countries, for the purpose of promoting literature, science, antiquities, and the fine and useful arts. These establishments have received the names of *academies*, *institutions*, and *societies*: and we have already described a great number of them in our article Academy. When this article was written, it was our design to give a similar article under the present head, and we have accordingly referred to it more than once. In the progress of the work, however, the authors of individual articles have, in general, described the societies established in particular cities, so that they have anticipated the greater number of those which might have been expected here. As the Royal Societies of London and Edinburgh, which, together with the Royal Irish Academy, (already described) form the three metropolitan institutions of Great Britain, have only been slightly noticed in our account of these cities, we shall now proceed to give a short account of them.

I. Royal Society of London.—This distinguished institution had its origin in 1645; but it was not till 1662 that it was established by royal charter. The Society held its first meeting at Gresham college in 1667. The following are the volumes of the *Philosophical Transactions* which it has published:—

From	1665 to	1678	-	12 volumes
	1683	1751	-	34
	1751	1800	-	44
	1800	1825	-	23
In all			-	113 volumes.

This valuable work, down to 1800, has been abridged by Drs. Hutton, Pearson, and Shaw, and published in 18 thick 4to volumes, with another volume containing a learned and interesting history of the Society by Dr. Thomas Thomson, in which the reader will find the most ample information respecting this institution.

The Royal Society of London adjudges three prizes, viz. the Copley medal, the Rumford medals, and the Royal medals.

1. The *Copley Gold Medal*, presented by Sir Godfrey Copley, Bart. who was a member of the Society from 1691 till his death in 1710. This medal used to be adjudged annually for the most important paper published in the transactions; but it has lately been adjudged to foreigners for discoveries not communicated to the Royal Society. The value of the medal is not above £5, 5s. It has been adjudged to many of the most distinguished ornaments of English science.

2. *The Rumford gold and silver medals.* These medals were presented by Benjamin Thomson, Count Rumford, in 1796, who presented L.1000 of 3 per cent. stock, the interest of which, or L.60, was to form a biennial prize "for the most important discovery or useful improvement in any way made known to the public during the two preceding years, on *heat* or on *light*." The form of the prize is a large gold and also a silver medal struck in the same die. As the medal has not been adjudged during eight of the biennial periods, the principal of L.1000 has been considerably increased, and as the interest of the additional sum is given along with the two medals, the prize is a very valuable one.

The following is a list of the philosophers who have received the Rumford medals:—

Count Rumford		
Professor Leslie	-	1804
M. Malus	- - -	1812
Sir Humphry Davy	-	1814
Dr. Wells	- -	1816
Dr Brewster	- -	1818
M. Fresnel	- -	1826

3. The *Royal Medals.* At the anniversary dinner of the Royal Society, on the 30th Nov. 1825, Mr. Peel announced his Majesty's intention of granting the sum of one hundred guineas annually, to establish two scientific prizes, to be awarded every year for the most important discovery or invention.

These medals were adjudged in
1826 to Mr. John Dalton, and
James Ivory, Esq., and in
1827 to Sir Humphry Davy.

The Royal Society of London have a valuable library. The admission fee, and the composition for the annual contribution of L. 5, 5s. amounts to about L. 50. The members receive the Transactions gratis, and authors of papers are allowed separate copies of them, but at their own expense.

II. Royal Society of Edinburgh.—In the year

1718, a Literary Society was established in Edinburgh by Ruddiman and others. In 1731, it was succeeded by a Medical Society. In 1739, the celebrated Colin Maclaurin and others extended it under the name of the Philosophical Society of Edinburgh, and between 1754 and 1771, they published three volumes of papers entitled *Essays or Observations, Physical and Literary.* In 1783, it was incorporated by a royal charter of the most degrading kind, being prohibited from forming either a library or a museum, and being bound to deposit the books presented to them in the Advocates' Library, and all objects of natural history in the College Museum! In 1811, this charter was rescinded and a new one obtained, which gave them the power of forming a library and a museum of their own; but it will scarcely be believed that at such a period of liberality, they are actually prohibited "from appointing a professor, lecturer, or doctor of mineralogy, geology, or natural history, or for using their collections to promote any such institution, excepting that which is, or shall be in the University of Edinburgh."

The Society has now a respectable library, and museum containing several objects of interest, which has recently obtained large and valuable accessions from the liberality of George Swinton, Esq. secretary to the government of Bengal.

The society has published the following Transactions:—

		Periods.	
From 1783	to 1788	5 years	1 volume
1788	1790	2	1
1770	1794	4	1
1794	1798	4	1
1798	1805	7	1
1805	1812	7	1
1812	1815	3	1
1815	1818	3	1
1818	1823	5	1
1823	1826	3	1
In all -	-	-	10 volumes.

The Royal Society of Edinburgh adjudges one prize, known by the name of the *Keith Medal.*

This prize was presented in 1819, by Alexander Keith, Esq. of Dunottar, an ardent lover and patron of science, and who was the first treasurer to the Society in 1783. He left L.1000 Sterling, under the management of Sir Alexander Keith, Dr. Keith, and Dr. Brewster, for the purpose of advancing the sciences and the arts of his native country. Out of this sum the trustees above mentioned offered L.600 to the president and council of the Society, the biennial interest of which, viz. L.60, was to form a biennial prize for the most important discoveries in science made in any part of the world, but communicated by their author to the Royal Society, and published in their Transactions. The trustees suggested that the form of the prize should be a gold medal, together with a sum of money, or a piece of plate, bearing the devices and inscriptions on the medal.

This offer was accepted by the Royal Society, and the Keith Medal was adjudged for the first time, in January 1828, to Dr. Brewster for his discovery of two new fluids existing in the cavities of several minerals, published in the 10th volume of the Society's Transactions.

The society consists of about 300 ordinary members, 21 honorary and 36 Foreign members. These two last classes are limited to the number mentioned.

The admission fee of £5, 5s. and the composition for the annual contribution of £3, 3s. amounts to about £36. The members receive the Transactions gratis, and the authors of papers receive 24 copies of them free of all expense.

Societies recently established in London.—Among the scientific societies recently established in London, and not described in that article, we may enumerate

Linnean Society, founded in 1788. Incorporated in 1802.

Entomological Society, founded in		1806.
Geological Society,	.	1811.
Horticultural Society,*	.	1804.
Royal Asiatic Society,		
Society of Civil Engineers,		1771 and 1793.
Zoological Society of London.		

Besides these, we may enumerate the following provincial institutions:—

Philosophical Society of Cambridge.

Literary and Philosophical Society of Leeds.

Natural History Society of York.

An account of the societies of Manchester, Newcastle, Plymouth, and the institution of Liverpool, will be found under these articles.

Societies recently established in Edinburgh.—Among the societies recently established in Edinburgh, and not described under that article, we may mention the

Caledonian Horticultural Society, established in† 1809.

Society for Promoting the Useful Arts in Scotland, founded in 1819.

Among the provincial institutions, may be mentioned the Literary and Antiquarian Society of Perth, already described in that article; and the Northern Institution of Inverness, a flourishing society established in 1825.

Among the other societies connected with Great Britain, we may notice, 1. the *Asiatic Society of Calcutta*, already described under that article, and which has published fifteen volumes of Transactions. 2. *The Medical and Physical Society of Calcutta*, established in 1823. This excellent institution has already published two volumes of Transactions in 8vo. containing many interesting papers. 3. *The Royal Society of Göttingen.* This society was established by George I. in 1751, and has published many volumes of commentaries in different series.

SOCIETY Islands, a group of islands in the Pacific, including Ulietea, Otaka, Bolabola, Huaheine, Tubai, and Maurua. Captain Cook gave them this name in 1769 from their contiguity. They lie in South Lat. 16° 30′, and 151° 30′ of West Long. The inhabitants, as well as the climate and productions of these islands resemble those of Otaheite. The first four of these islands have been converted to Christianity, the number of converts being above 5000. This happy change we owe to the zeal of the missionaries who distinguished themselves so much in Otaheite.

SOCINIANS. See Ecclesiastical History.

* See Horticulture.

† See Horticulture.

SOCOTRA, or SOCOTARA, an island in the Indian sea, is about twenty-seven leagues long and seven broad. Its surface is mountainous, and its precipitous shores afford many good harbours, of which Benin and Cora are the best. It has long been celebrated for its aloes, which are in great request. It yields also dragon's blood, ambergris, frankincense, and coral; and bullocks, goats, fish, rice, and dates may be obtained at reasonable prices. The town which is handsome, from the houses being built of stone, contains several mosques. The king's residence is in East Long. 53° 33', and North Lat. 12° 39'.

SOCRATES, an ancient moral philosopher of distinguished eminence, was born at Alopece a village near Athens, B. C. 469. His father Sophroniscus was a statuary, and his mother Phænaretta a midwife. Having lost his small patrimony by the dishonesty of a relation, he pursued his father's profession, and is said to have executed statues of the habited graces, which were thought worthy of a place in the citadel of Athens.

Crito, a wealthy Athenian, engaged him to educate his children, and in this situation he found leisure to attend the lessons of Archelaus and Anaxagoras, two of the most eminent teachers of the day. His valour was exhibited in saving the life of Alcibiades, and in carrying off Xenophon when left wounded on the field of battle; and his wisdom and integrity were equally conspicuous when he served his country in the senate of 500.

Afflicted with the moral and intellectual condition of his countrymen, Socrates resolved to become a public instructer at Athens, by conversation and by public lectures addressed at all seasonable times to all classes of the community, from the mechanic up to the senator. In these communications with his fellow citizens, his object was to convince his hearers of their individual follies and vices, to inspire them with a love of virtue, and to impress upon them the conviction of the narrow limits of the human understanding. His plan consisted in asking a series of questions, and in gaining the assent of his pupils to certain truths which they themselves could not but deduce from their own previous admissions; and such was the skill with which he often concluded these examinations, that his pupil was not aware of the conclusion till he found it irresistible upon his own principles.

The humility which characterised the deportment of this great man, the uniform excellence of his conduct, the abstemiousness of his life, and his contempt of wealth and popular applause, point out Socrates as one of those superior beings whom Providence occasionally exhibits to the world as an example for future ages. "The man," says Xenophon, "whose memoirs I have written, was so pious that he undertook nothing without asking the counsel of the gods; so just, that he never did the smallest injury to any one, but rendered essential services to many: so temperate, that he never preferred pleasure to virtue; and so wise, that he was able in the most difficult cases, without advice, to judge what was expedient and right. He was eminently qualified to aid others by his advice; to penetrate into men's characters: to reprehend them for their vices, and to excite them to the practice of virtue. Having found all these excellencies in Socrates, I have always regarded him as the most virtuous, and the happiest of men."

It was not to be expected that the enemy of public immorality, and of political corruption and oppression, could escape the hostility of those who smarted under the exposure of their vices. The immoral youth of Athens hired Aristophanes to lampoon him on the stage, in the comedy of the "Clouds," written for this purpose. Socrates himself attended the performance of the piece, and when the person who represented himself appeared upon the stage, Socrates stood up to exhibit the original of the character to the inquiring audience. When he was asked by a spectator if he was not chagrined at this public derision, he replied, "By no means, I am only a host at a public festival, where I provide a large company with entertainment."

Baffled in this attempt to disgrace the philosopher, the malice of his enemies was directed into a new channel. He was publicly accused before the senate, by one Melitus a rhetorician, of "not acknowledging the gods which the state acknowledges; of introducing new deities, and of violating the laws by corrupting the youth." Anylus, a leather-dresser and the principal accuser, offered to withdraw the charge if Socrates would desist from censuring his conduct: but Socrates replied, that "while he lived he never would disguise the truth, nor speak otherwise than his duty required."

On the day of the trial, Plato rose to address the court in favour of his master, but he was soon commanded to sit down. Socrates then made his own defence, and unveiled in the most powerful manner, the characters and motives of his accusers. A corrupted and unjust court, however, who had predetermined his death, listened not to the truth; and Socrates was condemned to be poisoned by hemlock.

The friends of Socrates endeavoured to persuade him to make his escape, or at least to allow them to carry him off from his enemies. He rejected, however, the proposal as a violation of the law, and resolved to submit himself to its decrees.

His friends and disciples repaired to his prison, to hear the last words of their great master, and on this occasion the conversation turned principally on the immortality of the soul. Socrates condemned the practice of suicide, and assured his friends that his chief support was the expectation, not free from doubts, of a happy existence after death. "It would," he said, "be inexcusable to despise death, were I not persuaded that it would lead me into the presence of the gods, who are the most righteous governors, and into the society of just and good men; but I confide in the hope that something of men remains after death, and that the condition of good men will then be better than that of the bad." When Crito asked him how he wished to be buried, Socrates replied with a smile, "According to your pleasure, provided I do not escape out of your hands." Then addressing himself to the rest of the party, he said, "Is it not strange, after all that I have said to convince you, that I am going to the society of the happy, that Crito still thinks this body, which will soon be a lifeless corpse, to be Socrates? Let him dispose of my body as he pleases; but let him not at its interment mourn over it as if it were Socrates."

After retiring to an adjoining apartment to bathe, he took his last leave of his friends, and then having prayed for a prosperous passage into the invisible world, he drank the fatal poison without the least change of countenance or apparent discomposure. His friends around him burst into tears. Socrates alone was unmoved. He upbraided their weakness, and implored them to exercise a manly fortitude worthy of the friends of virtue. He continued walking till the influence of the hemlock forced him to lie down upon his bed. After remaining silent for a short time, he requested Crito not to neglect the offering of a cock, which he had vowed to Esculapius. Then covering himself with his cloak he expired. This event, the account of which Cicero assures us he never read without tears, took place in the year 399 B. C.

The Athenians were roused to a sense of their shame, in having destroyed one of the greatest of their citizens. Melitus was condemned to death, and Anyles escaped the same fate only by voluntary exile. The Athenians recalled the friends of Socrates from exile, decreed a general mourning, and erected a statue to his memory. See *Pausanias* 1, cap. 42. Plutarch, *De Op. Phil.* &c. Cicero, &c. Cret. 1, c. 24. Tusc. Quest. 1, c. 41, *Valerius Maximus*, 3, c. 4, and Brucher's *History of Philosophy*, by *Enfield*, vol. i. See also our articles Athens, and Greece.

SOGDIANA, a county of Asia, between the rivers Iaxartes and Oxus. It was bounded on the north by Scythia, on the west by Morgiana, on the south by Bactriana, and on the east by the Sacæ. Maracanda was the capital of the country. It is now called Sogd, and is part of the country of Great Bucharia.

SOHAM, or Monks Soham, a town of England, in the county of Cambridge, situated on the east side of the Cam. It is large and irregularly built, and has a spacious church, with a tower at the west end. Its principal street is three-fourths of a mile long. There is here a large charity school, and three alms-houses. Cheese of excellent quality is the principal produce of the place. Population of the town in 1821, 2856. Houses 537. Families 691. Do. in trade 107.

SOIL. See Agriculture Index.

SOISSONS, the *Noviodunum* of Cæsar, a town of France, in the department of the Aisne. It stands in a fine valley, traversed by the Aisne. The public buildings are the cathedral, with a library and a collection of manuscripts, the church of Notre Dame, the academy established in 1679, a lyceum, and a theatre. Its manufactures are leather, coarse linen, ropes, stockings, and thread. Corn is exported in considerable quantities. Its haricots are celebrated. Near Soissons is St. Gobin, celebrated for its glass manufactory. Population 8189.

SOLDER is the name of a metallic compound, used to join together other metals. The following are some of the most important of the solders, it being a general principle that some of the metals to be soldered should be mixed with some higher and finer metals.

1. *Solder for gold* consists of fine *gold*, with one-fourth or one-half its weight of fine silver, mixed by fusion, and beat out into leaves thinner than card paper, and rendered soft by annealing. A portion is then laid on the fracture, or ends to be united, and it is sprinkled with pulverized borax. The flame of a blow-pipe is then used to melt the whole. The borax is removed by boiling water, or a little dilute sulphuric or muriatic acid; and the paler colour of the solder may be deepened, by melting on its surface a mixture of two parts of nitre, and one of burnt alum, and washing it off with hot water. Silver after soldering, may be cleansed by boiling it in alum water, and gold by urine and salammoniac.

Solder for gold may also be made with gold and a little copper.

2. *Solder for Steel and Iron.*—Gold with a slight alloy of copper is a good solder for uniting the finer kinds of steel instruments. For larger articles in iron and steel, an alloy of equal parts of tin and iron is used.

3. *Solder for Plumbers.*—This solder consists of *two* parts of *lead*, and *one* of *block tin.* It is known to be good when small bright shining stars rise in a small piece of it poured out of the crucible in which it is melted. Equal parts of lead and tin are used when it is wished to be hard; and when it is wanted to be very fusible, bismuth is added in various proportions.

4. *Solder for Silver.*—The *hard* kind is composed of equal parts of silver and fine brass, and the *soft* is made by fusing the hard solder with one-sixteenth its weight of pure zinc.

A *second* solder for silver is made of two parts of fine silver, and one of brass, which must not be kept long in a state of fusion. lest the brass be oxidated.

A *third* solder for coarser silver is made of four parts of fine silver, three of brass, with a little borax, and it must be poured out when melted.

5. *Solder for copper.* This is made of copper and tin; but for fine work silver is substituted for tin.

6. *Solder for copper, brass, and the hard alloys of copper.* The best hard solder for these purposes is made of brass and zinc, from eight to sixteen parts of brass to one of zinc, according to the hardness required. The soft solder consists of three parts zinc and one lead, and is applied by a common red hot soldering iron.

7. *Solder for organ pipes.* This is made of three parts pewter and one bismuth.

8. *Soft pewterer's solder*, is composed of two parts tin and one bismuth, which is very easily melted.

9. *Spelter solder.* This is made of two-parts of spelter, (the commercial name for zinc.) and one of brass. It is used by braziers and coppersmiths for brass, copper, and iron. A dwt. of silver to each oz. improves it greatly.

SOLEURE, in German, *Solothurn*, is the name of a canton of Switzerland. It lies between the Aar and the Jura, partly occupying the plain and partly the face of the ridge. Its surface is about 275 square miles. The land is partly arable and partly devoted to pasturage, which is greatly improved by an excellent system of irrigation. The cattle thus reared are deemed the best in Switzerland. The manufactures are woollen, linen, and cotton goods. Soleure and Olten are the principal towns. Olten is beautifully situated on the banks of the Aar, with the finely wooded peaks of Jura rising behind it. The Aar is here crossed by a wooden bridge of six arches roofed in with wood. Olten has a new church with two small towers, a gate with a high square turret and another small tower. The population is 1300. The inhabitants are chiefly catholics, and amount to 50,000.

SOLEURE, the *Solodurum* of the ancients, and the capital of the above canton, is finely situated on the Aar, which divides it into two parts. It is fortified with walls and bastions, the walls inclosing about fifty acres. It is tolerably well built, and the houses are generally neat. The principal buildings are the Hotel de Ville, the public jail, the Jesuits' church, the church of St. Urse, the mint, and the public library, containing above 11,000 volumes, and the great square Roman tower. The church of St. Urse, begun in 1762, and finished in 1772, is a noble edifice of whitish grey stone, the lower part being of the Corinthian, and the upper of the Composite order. The façade, which consists of a portico surmounted by an elegant tower, faces the extremity of the principal street. The expense is said to have been L.80,000. The vicinity of the town is beautiful; and the traveller should ascend to the Chalets and farm of Weissenstein. From this is the finest view in Switzerland, embracing the immense valley which separates Jura from the high chain of the Alps, together with the snowy mountains. At sunset this scene baffles all description. See *Dict. de la Suisse*, Art. Soleure. Coxe's *Travels in Switzerland*, vol. i. and Ebel's *Manual*, &c. vol. iv.

SOLWAY Moss, a tract of land in Cumberland, celebrated for an eruption of a very remarkable kind, which is thus described by Mr. Gilpin.

"Solway Moss is a flat area about seven miles in circumference. The substance of it is a gross fluid, composed of mud and the putrid fibres of heath, diluted by internal springs, which arise in every part. The surface is a dry crust, covered with moss and rushes, offering a fair appearance over an unsound bottom, shaking with the least pressure. Cattle, by instinct, know and avoid it. Where rushes grow the bottom is soundest. The adventurous passenger, therefore, who sometimes, in dry seasons, traverses this perilous waste, to save a few miles, picks his cautious way over the rushy tussocks as they appear before him. If his foot slips, or if he ventures to desert this mark of security, it is possible he may never more be heard of. On the south, Solway Moss is bounded by a cultivated plain, which declines gently through the space of a mile to the river Esk. This plain is lower than the moss, being separated from it by a breast-work, formed by digging peat, which makes an irregular though perpendicular line of low black boundary. It was the bursting of the moss through this peat breast-work, over the plains between it and the Esk, that occasioned the dreadful inundations that destroyed so large a district. The more remarkable circumstances relating to this calamitous event were these:—

On the 13th of November 1771, in a dark tempestuous night,* the inhabitants of the plain were alarmed with a dreadful crash, which they could no way account for, many of them were then in the fields watching their cattle, lest the Esk, which was then rising violently in the storm, should carry them off. In the meantime, the enormous mass of fluid substance, which had burst from the moss, moved slowly on, spreading itself more and more as it got possession of the plain. Some of the inhabitants, through the terror of the night, could plainly discover it advancing like a moving hill. This was, in fact, the case; for the gush of mud carried before it, through the first two or three hundred yards of its course, a part of the breast-work, which though low, was yet several feet in perpendicular height; but it soon deposited this solid mass, and became a heavy fluid. One house after another it spread round, filled, and crushed into ruins, just giving time to the terrified inhabitants to escape. Scarcely any thing was saved except their lives; nothing of their furniture, few of their cattle. Some people were even surprised in their beds, and had the additional distress of flying naked from the ruins. The morning light explained the cause of this amazing scene of terror, and showed the calamity in its full extent; and yet, among all the conjectures of that dreadful night, the mischief that really happened had never been supposed. Lands which in the evening would have let for twenty shillings an acre, in the morning were not worth sixpence. On this well-cultivated plain twenty-eight families had their dwellings and little farms; every one of which, except perhaps a few who lived near the skirts of it, had the world totally to begin again. Who could have imagined that a breast-work, which had stood for ages, should at length give way? or that these subterraneous floods, which had been bedded in darkness since the memory of man, should ever have burst from their black abode? This dreadful inundation, though the first shock of it was most tremendous, continued still spreading for many weeks, till it covered the whole plain, an area of 500 acres, and like molten lead poured into a mould, filled all the hollows of it, lying in some parts thirty or forty feet deep, reducing the whole to one level surface." Gilpin's *Observations on the Mountains and Lakes of Cumberland*.

In order to clear the arable and pasture land of this accumulation of moss, Mr. Wilson from Yorkshire, adopted a very ingenious plan. He formed, in the higher grounds, two large reservoirs, which he filled with water, the whole force of which he directed against a large knoll in front of Netherby House, and afterwards against the accumulated masses, which he succeeded in washing away into the channel of the Esk. Dr. Graham of Netherby had sent for a person to survey the ground, and estimate the expense of removing the moss in the ordinary way. The estimate was L.1300; but while the matter was under consideration Wilson suggested that it might be done cheaper, and by the method which we have mentioned he effected it for less than L.20!

Another account of the eruption of this moss, by Mr. J. Walker of Moffat, will be found in the *Philosophical Transactions* for 1772, vol. lxii. p. 123. According to Mr. Walker, the mossy ridge was reduced no less than twenty-five feet; but what is not easily explained, he makes the eruption take place on the 16th December 1772, whereas Gilpin places it on the

* Three days rain of unusual violence preceded the eruption. Ed.

13th November 1771. Mr. Walker mentions the remarkable case of a cow, the only one out of eight in the same byre that was saved. It had stood *sixty hours* up to the neck in mud and water; and when it was taken out it did not refuse to eat, but it would not taste water, nor even look at it, without manifest signs of horror. It was soon, however, reconciled to it, and was then likely to recover.

SOMERSETSHIRE, a maritime county of England, is bounded on the north by Gloucestershire and the Bristol Channel, on the east by Wiltshire, on the south-west by Devonshire, and on the south-east by Dorsetshire. It is one of the largest counties in England, its greatest length from east to west being about 68 miles, and its breadth from north to south 47 miles; it is 240 miles in circumference, and it is computed to contain 1,050,880 English acres.

This county is divided into two civil divisions, the eastern and the western; in the first there are 20 hundreds and seven liberties, in the second 22 hundreds. Somersetshire possesses two cities, Bath and Wells, and a part of Bristol, seven boroughs, and 29 market towns. The ecclesiastical divisions are one bishopric, three arch-deaconries, 13 deaneries, and 482 parishes. The county is in the province of Canterbury, and the diocese of Bath and Wells. Bath contains two deaneries, Wells seven, and Taunton four.

Few counties present a more diversified aspect or a greater variety of soil, changing from the highly cultivated valley to the barren and stony heath, and to the bleak and lofty hills so seldom to be met with in other parts of England. In the north-east corner are the lofty Mendip Hills, which are chiefly remarkable for the quantity of coals and lead they produce. The other hills of note are Quantock, on the western side of the county, Brendon, near Quantock; Poulden, near Bridgewater, Broadfield-Down, between Bristol and Wrington; Leigh-Down, in the hundred of Portherry; Dundry, near Bristol; Lansdown, near Bath; White-Down, near Chard; and Black-Down, on the confines of Devonshire. Near the Quantock hills is a dreary heath called Exmoor Forest, a part of which, called Dunkeny, is 1668 feet above the level of the sea, and from which there is a fine view of the adjacent country, extending as far as the Bristol channel on one side, and the English channel on the other. The bleakness and sterility of these hills, however, is amply compensated by the luxuriance of the meadows and the fertility of the arable lands, which produce such abundant crops as are sufficient not only for the consumption of the inhabitants, but even for supplying other markets. The general appearance of the country is rich, rather than picturesque, owing, in a great degree, to the scarcity of woods and the sluggishness of the streams, which in summer become nearly stagnant, and thereby greatly diminish the beauty of the landscape.

The chief rivers are the lower Avon, the Ax, the Brue or Brent, the Parret, the Yow, the Cale, Chew, Tone, Frome, Ivel, Ex, and Barl. The lower Avon is a navigable river, and rising in the north of Wiltshire, near Wootton Basset, becomes navigable at Bath, and running on with a circuitous course, it passes Bristol, and empties itself into the Severn, forming the Bristol channel at Kingsroad by its conjunction with that river. The Ax rises in the Mendip hills, and has its chief source in a natural excavation called Wookey Hole, which bears some resemblance to the caves of Derbyshire. This river is not navigable. The Brue or Brent has its origin in Wiltshire, and enters the Bristol channel at Bridgewater Bay; it is navigable for about two miles from its mouth. The Parret rises near the village of south Parret in Dorsetshire, and after its junction with the Tone, runs into Bridgewater Bay through the marsh of Sedgemore. It is navigable from Stert point to Langport, a distance of about 20 miles. These rivers all abound with trout, salmon, perch, pike, carp, tench, and other smaller fish. The only canal that Somersetshire can boast of is the Kennet and Avon, which joins the Thames with the Severn.

As this county has long been famous for the richness of its meadow lands and the abundance of its grass, the fattening of cattle and the management of the dairy has, of necessity, become the most important branch of its rural economy. The oxen bred in the less favoured pasturages of Devonshire afford excellent beef when fattened in this district; and supply not only the neighbouring markets, but even those of London. The sheep natural to the county are of the Mendip breed, but of late years almost every improved variety has been introduced. The dairies are not less remarkable for the superior excellence of their butter and cheese, the cheese of Cheddar having long enjoyed the reputation of being equal to any in England, and is often sold at Gloucester; the butter made in the vicinity of Crewkerne is sent to the London dealers, who sell it under the name of Dorsetshire butter. Among the agricultural products, the cider, which is reckoned superior in strength and purity to that either of Herefordshire or Devonshire, is not the least important, as it is the principal drink of the lower orders throughout the whole county. The natural grass is so plentiful, that it has almost entirely superseded the use of clover or other artificial grasses. Barley is not much grown, but wheat, oats, and bear, together with flax, teazels, and woad, are cultivated very extensively in most parts of the county. The hundred of Taunton Dean is reckoned to produce the best crops of wheat. Elm trees thrive best in the rich loamy soils, which are also particularly well adapted to the growth of flax, most of which is used in the manufactures of the county. Geese feathers formerly yielded a considerable profit, but as many of the marshes were drained and inclosed a few years ago, and as many are now undergoing the same process, the supply of feathers is not nearly so great as it was when the county abounded with marshes, which are necessary for the subsistence of the geese, and which, in their present state, afford much more profit to their owners than before.

Somersetshire is by no means deficient in mineral products; the Mendip Hills abound with lead, coal, and calamine. The lead is chiefly exported for the purpose of making bullets and shot, and the calamine is used by the brass manufacturers of Bristol. The coals supply the cities of Bath and Wells, and the towns of Frome and Shepton Mallet. Lead is also raised on the Cheddar Hills of a finer quality than that of Derbyshire. Manganese, bole, and red ochre, are found on the Mendip Hills, and copper near Stowey. Limestone, fuller's earth, and marl, are procured in other parts of the county.

Somersetshire is almost entirely a manufacturing county. At Frome, Shepton Mallet, and their neighbourhood, there are extensive manufactories of cloths of Spanish and Saxon wool. Ilminster, Chard, Taunton, and Wellington, produce woollen cloths of a middle quality, while others of an inferior description are made at Wevesleombe, Milvarton, and Watchel. Linen goods, such as dowlas, bedtickings, and sail cloths, are manufactured at Yeovil, Crewkerne, Montacute, and Martock. There are silk mills at Bruton and Taunton; and gloves are made at Yeovil. Chard and Wells both possess manufactories, one for wove lace, the other for fine paper; a quantity of valuable articles are made at the glass houses near Bristol. At Bridgewater, there is a foundry and a braziery, which give employment to a number of people.

The foreign commerce of this county is chiefly carried on at Bristol, which is the place from which such goods as are eligible for the foreign market are generally exported, with the exception of the woollen articles made at Taunton and Wellington, which are exported from Exeter. Bridgewater enjoys a trade with Ireland, and many of the smaller sea-coast towns, a coasting trade which they turn to a considerable account. The greatest part of the productions of the county, both agricultural and manufactured, which are not destined for home consumption, find a ready sale at the markets of the adjacent counties. The cattle, butter, and cheese, are sent to the metropolis. Wales and the western counties are supplied with the linen and woollen manufactures.

The parliamentary representatives are two for the county, and two for each of the undermentioned towns, viz: Bath, Wells, Taunton, Bridgewater, Ilchester, Minehead, and Milborn Port, and two for Bristol, which is partly in this county, and partly in Gloucestershire.

Ilchester is considered the county town, as the elections are held there, and as it contains the gaol and county court, although the assizes are held at Taunton in spring, and in the summer season at Bridgewater and Wells alternately.

The population in 1821, was 355,314, of whom there were 152,447 males, and 165,357 females. The inhabited houses were 61,852, the uninhabited 1974, and houses building 850. The number of the families was 73,537, of whom 31,448 were employed in agriculture, 27,132 in trade, and 14,957 in neither of the above classes. See Bellingsley's *Account of the Agriculture of Somersetshire*, and the *Beauties of England and Wales*, vol. xiii.

SOMERSET, county of the United States in Maine. It would be not merely useless, but deceptive to give a description of this county, with its present extent, as the advance of settlement must superinduce perhaps 8, 10, or more counties from its limits. When the census of 1820 was taken, Somerset county extended from Kennebec northward to the extremity of the state, stretching 180 miles in length, with a breadth exceeding 50, and embracing between 7000 and 8000 square miles. But of this great extent, only the southern part was inhabited, and sustained a population of 21,187. The inhabited tract, traversed by the Kennebec river, is a fine, it might be said, beautiful country, and in a state of rapid improvement. Seat of justice Norridgewock. N. Lat. 45° and Long. 7° E. from Washington City, intersect near the Kennebec river in this county, and about 30 miles a little W. of N. from Norridgewock.

SOMERSET, county of the United States in New Jersey, bounded by Middlesex SE., Hunterdon W., Morris N., and Essex North-east. Length 30, mean width 12, and area 360 square miles. This county extends lengthwise from N. to S. and is drained by the various confluents of Rariton river. The face of the country agreeably diversified by hill, dale, and even mountain scenery, render Somerset county of New Jersey one of the most pleasant to the eye of the inland counties of the United States. In 1820, the population amounted to 16,506, or within a very small fraction of 46 to the square mile. The agricultural products are various and valuable, and occupying a nearly central position between New York and Philadelphia, the farmers find a ready market. Somerset divides the city of New Brunswick with Middlesex, and besides the seat of justice, Somerville, has the villages of Boundbrook and Middleburg, with part of Princeton. Central Lat. 40° 35′ N. Long. from Washington City 2° 25′ E.

SOMERSET, county of the United States in Pennsylvania, bounded by Alleghany county in Maryland S., by Fayette county in Pennsylvania SW., Westmoreland NW., Cambria NE. and Bedford E. Length from south to north 35, mean width 26, and area 910 square miles. Embracing a large part of an extensive valley between that particular ridge of the Appalachian system of mountains called the Alleghany, and another lateral ridge, the Laurel hill, the surface of Somerset county of Pennsylvania is a true mountain table land, elevated at a mean of at least 1500 feet above the tides of the Atlantic coast, and upwards of six hundred and sixty feet above the level of the Monongahela at Brownsville. This relative height gives to Somerset a climate near, if not altogether, four degrees of Fahrenheit more severe than that of similar latitude on the eastern coast of New Jersey. The 40th degree of North Lat. and two degrees of Long. W. from Washington City, intersect near the centre of Somerset. The middle parts of New Jersey, will therefore contrast with the southern mountain valleys of Pennsylvania. The comparative tropical climate of the former is usually ascribed to proximity and absence of an open ocean, a cause perhaps of a share of the effect, but difference of level is the far more efficient agent.

A very small angle of the south-east part of Somerset is drained by Wills creek branch of Potomac: Youghioghany river, rising in Virginia and Maryland, flows north into Pennsylvania, forming for 8 or 9 miles part of the boundary between Fayette and Somerset counties, receiving from the latter a large confluent, Castleman's river. The northern section towards Cambria is drained by the south-eastern sources of Conemaugh river. Though bounded by two mountain ridges, Somerset is rather level than even hilly. The soil is various, and generally well adapted to grain and meadow grasses.

The intended Chesapeake and Ohio canal is projected to pass over the southern part of Somerset by the valley of Castleman's river.

Somerset, the seat of justice, is situated near the centre of the county, N. Lat. 40°. Long. W. from

Washington City 2° 05′ Population of the county, 1820, 13,374, or 15 to the square mile nearly.

SOMERSET, county of the United States, on the eastern shore of Maryland, bounded by Worcester county in the same state E., Chesapeake bay S. and W., Nanticoke river, or Dorchester county, Maryland, NW., and Sussex county, Delaware, N. This county lies between the Pocomoke and Nanticoke rivers, and is cut into three peninsulas by the Wicomico and Monokin rivers. The surface is flat and sandy, though generally productive. From the indentings of the bays or river mouths, the area is estimated with some difficulty; the length from the Pocomoke inlet to the Delaware line 30, and mean width 15, with an area, exclusive of water, of about 450 square miles. Central Lat. 38° 16′. Long. E. from Washington City 1° 18′. Seat of justice, Princess Anne.

DARBY.

SOMME, the name of one of the departments in the north of France, is bounded on the north by the Straits of Calais, on the west by the sea and the department of the Lower Seine, on the south by that of the Oire, and on the east by that of the Aisne. In point of agriculture and manufactures this is one of the most flourishing departments in France. Tillage and the feeding of cattle are carried on as in Flanders. The surface contains 604,456 hectares. The principal river is the Somme, whence it derives its name. The chief towns are

	Population.
Amiens	40,289
Abbeville	18,052
Doullens	2,946
Montdidier	4,049
Perrone	3,706

The forests occupy 57,000 hectares, and the contributions in 1803 amounted to 5,630,664 francs. The population in 1822, was 508,910, and in 1827 526,282; there being 860 inhabitants to every 1000 hectares. See ABBEVILLE and AMIENS.

SOMNAMBULISM is that state of the body in which it *walks* during *sleep*, and performs many voluntary actions without any consciousness of performing them, or any recollection of their having been performed.

In this state of the body the patient rises from bed, opens doors, windows, or drawers, walks into the fields, sits down to write, crosses hedges, walks along the tops of houses, ascends precipices, climbs to rooks' nests, and performs feats from which he would shrink in his waking moments. To these we may add the delivery of sermons and prayers during sleep, a power possessed, and for many years exercised, by an American lady. Dr. Park is of opinion that "the physical cause of this singular affection appears to be an irregular distribution of blood in the sensorium, or some local congestion that impedes the uniform and simultaneous restoration of the corporeal and mental faculties." Those who wish to study the subject may consult Hoffmann's *Dissertatio de Somnambulismo*, in the Suppl. to his works, vol. iii. Art. *Somnambulism* in the Encyclopedie. Cleghorn, *De Somno*, Edin. 1783, Darwin's *Zoonomia*, vol. i. Sect. 19. in Dugald Stewart's *Philosophy of the Human Mind*, chap. v. and Dr. Park in the *Quarterly Journal*, vol. vii. p. 258. See also our article DREAMS.

SONORA and SINALOA, (*Sonora y Sinaloa*,) nominally a state of the Republic of Mexico, but in fact an immense, and towards the northern part, but imperfectly known section of North America, exceeding in extent the whole Atlantic section of the United States. As laid down and coloured on Tanner's map of Mexico, Sonora and Sinaloa extends from N. Lat. 21° 40′ to 39° 40′, or through 18 degrees of latitude, and limited on the north-west by the Red river of the Gulf of California, (*Rio Colorado*,) and W. by the Gulf of California. It touches the states of Jalisco and Durango on the south-east, with Chihuahua and New Mexico stretching along the eastern border. Thus restricted, this country reaches from South to North over 1250 miles with a mean width of at least 200, and embraces an area of 250,000 square miles.

Restricting Sonora y Sinaloa to the Colorado river, however, leaves an unnamed region of Mexico south from N. Lat. 42°, which if included would give the state under review a superficies of at least 300,000 square miles. The following will be confined to the region between the Gulf of Bayona, and the Rio Gila.

According to Humboldt, the Intendancy of Sonora comprehended the three provinces of Cinaloa, or Sinaloa, Ostimury, and Sonora Proper. Sinaloa reached from the Rio del Rosario to the Rio del Fuerte. Ostimury occupied the narrow space between the Rio del Fuerte and the Rio Mayo. Sonora, more anciently New Navarre, included all the northern extremity of the Intendancy.

Sonora and Sinaloa is a hilly rather than mountainous country, and from either the meagre description of Humboldt or its representation on our maps, is in a great degree devoid of large navigable rivers. The Rio Gila rises in the Sierra de los Mimbres, between N. Lat. 32° and 34°, 31° W. from Washington City, and flowing westerly about four hundred miles, falls into the estuary of the Rio Colorado, N. Lat. 32° 50′. At a long interval of upwards of four hundred miles, flowing the coast SSE. with the small river Ascension excepted, there is no stream worthy notice from the mouth of the Rio Gila to that of the Hiaqui.

The Rio Hiaqui has its remote sources in the same chain with those of the Gila, but the former pursues a course of SW., four hundred miles, into the Gulf of California, which it enters opposite Cape St. Miguel, N. Lat. 27° 40′. It is probable that as a navigable entrance the Hiaqui is of little importance, as no city or extensive settlement has risen on its banks. From the outlet of Hiaqui to the Gulf of Bayona, in a distance of five hundred miles, several petty rivers flow from the interior, but are of minor value regarded commercially.

The Gulf of California, the American *Red Sea*, is, in geographical strictness, the continuation of the Rio Colorado, and stretches along Sonora and Sinaloa, 800 miles from the mouth of the Rio Gila, to a line from Cape Palmas to the port of Mazatlan, where it terminates in the Pacific Ocean, N. Lat. 23° 15′. The Californian Gulf is narrow and much chequered with islands, and represented as of difficult and dangerous navigation. Between Cape Palmas, the south-eastern point of the peninsula of California, to the opposing shore of Sinaloa, the Gulf is 120 miles wide, but at Cape St. Miguel, and at the Tiburon islands, not above 40, and may, in all its length, average a mean breadth of 60 miles, or an area of 48,000 square miles.

If the mental eye is turned to a map of North America, and the courses of the Colorado and its recipient. the Gulf of California, are taken in connexion, with the great western confluents of the Mississippi, the conclusion follows, that in the advance of population and improvement, the greatest facility to an inland communication between the United States and the Pacific ocean, is offered by the route of Sonora and Sinaloa. If the view of the map of America is extended to that of the world, it will be seen, that a commercial chain extended from St. Louis on the Mississippi, over the Colorado basin stretches towards China, India, and Polynesia, and merges into the Pacific Ocean twenty-three degrees of latitude more southwardly than by the Columbia.

The population of this region is stated by Humboldt (1803-5) at 121,400; in Tanner's map of Mexico the inhabitants of Sonora and Sinaloa are given in a subjoined table at 188,636. Neither adduce their authority or inform us whether the independent Indians are included, or whether the estimate is restricted to the whites and subject tribes of natives. If, however, only the latter are included, the distributive population must be very thin. Humboldt (1803) our only authority for the condition of this remote country, has passed the mental state of the whites in silence, but observes that "the Indians who live on the plains adjoining the Cases Grande of the Rio Gila, and who have never had the smallest communication with the inhabitants of Sonora, deserve by no means the appellation of savages. (*Indias bravos.*) Their social civilization forms a singular contrast with the state of the savages who wander along the banks of the Missouri." The Spanish missionaries who have been able to reach this interesting region, represent the inhabitants as civilized, and social, residing in villages formed of good houses and environed by well cultivated fields. More, these Indians were found clothed in cotton fabrics of their own manufacture. These favourable accounts have been recently confirmed by some travellers from the United States.

This domestic and advanced civilization cannot be of recent origin. "Father Francisco Garces, accompanied by Father Font," says Humboldt, "who was intrusted with the observations of latitude, set out from the Presidio d' Horcasitas, on the 20th of April, 1773. After a journey of eleven days, they arrived at a vast and beautiful plain, one league's distance from the southern bank of the Rio Gila. They there discovered the ruins of an ancient Aztec city, in the midst of which is the edifice called *la Casa grande.* These ruins occupy a space of ground of more than a square league, ($7\frac{1}{4}$ *square miles nearly.*) The Casa grande is exactly laid down according to the four cardinal points, having from north to south 445 English feet, and from east to west 276 feet. The walls are of clay, constructed in *Pisé* 3 feet 11 inches thick. The edifice had three stories and a terrace. The same kind of construction is still to be found in all the villages of the Independent Indians of the Moqui west from New Mexico. A wall, interrupted by large towers, surrounds the principal edifice, and appears to have served to defend it. Father Garces discovered the vestiges of an artificial canal, which brought the water of the Rio Gila to the town. The whole surrounding plain is covered with broken earthen pitchers and pots, prettily painted in white, red, and blue. We also find amongst these, fragments of Mexican stone ware, pieces of obsidian, (itztli,) a very curious phenomenon, because it proves that the Aztecs passed through some unknown northern country which contains this volcanic substance, and that it was not the abundance of obsidian in New Spain which suggested the idea of razors and arms of itztli.

"We must not," continues Humboldt, "confound, however, the ruins of this city of the Gila, the centre of an ancient civilization of the Americans, with the Casas grandes of New Biscay, situated between the presidio of Yanos and that of San Buenaventura." Between these points are spread plains and mountains in a distance of upwards of one thousand miles.

Gold is amongst the productions of Sonora and Sinaloa. The hilly country of Pimeria alta is the Choco of North America. All the ravins and even plains contain gold scattered up and down the alluvious land. Fragments are discovered weighing from five to eight pounds Troy.

The most remarkable places of Sonora are Arispé, the former capital of the state, N. Lat. 30° 36′, Long. W. from Washington City 31° 38′, upwards of one thousand miles NNW. from the city of Mexico. Population 8,000.

Sonora the present capital of Sonora proper is situated about 50 miles south from Arispé. Population 6,400.

Hostimury, or Ostimury, is a mining town and capital of the province of the same name, situated on the Pacific ocean, N. Lat. 27°.

Sinaloa, or Cinaloa, otherwise known by its ecclesiastical name of *Villa de san Felipe y Santiago*, is now the capital city of the state of Sonora and Sinaloa, containing a population of 13,000; and is situated at N. Lat. 26° 58′, and Long. W. from Washington City 30° 57′, upwards of five hundred miles NW. from the city of Mexico.

About one hundred and twenty miles SE. from the city of Sinaloa, stands Culiacan, the Aztec Hueicolhuican, on a small river of the same name. It is still a place of some consequence as the population was stated by Humboldt at 10,800.

On the small river del Fuerte, 70 or 80 miles NW. from the city of Sinaloa, is situated a considerable town, Montesclaros, or Villa del Fuerte, with a population of 8,000; and 70 miles still farther NW. is Alamos, sustaining 8,000 inhabitants.

A Rosario, near the rich mine of Copala, and approaching the southern extremity Sinaloa and about 200 miles SE. from the city of Sinaloa, contains a population of 6,000.
